The second possibility is to use small vehicles, usually busses, as feeders, transferring the passengers to a few trunk routes, on which the traffic will be heavy enough to warrant frequent service with larger and more economical units. The disadvantage of this plan is that a large proportion of the passengers must transfer.

A third method is to use a terminal system,[1] as that proposed by A. V. Eastman, in which all lines from the outlying districts terminate in two or more terminals located near, but still outside, the metropolitan area. Heavy trunk-line service is provided between these terminals, over several alternate routes so spaced as adequately to cover the metropolitan district.

Speed. Much of the appeal of the private automobile, aside from its convenience, is due to its superior speed. Although speed is important in a transit vehicle, it must not be attained at a sacrifice of safety. Owing to the large number of stops which it must make, no public conveyance in use on city streets will ever be able to equal the speed of the private automobile. A high schedule-speed (by schedule-speed is meant the average speed including all stops, layovers, etc.) is desirable for two reasons; first, it speeds the passenger to his destination, and second, it reduces the cost of giving service. Costs are reduced because both the number of cars required to run a given service and the amount of platform labor are decreased.

The schedule-speed of modern transit vehicles is much superior to that of their predecessors. For example, the Presidents Conference Committee car, usually called the PCC car, is designed to have a schedule-speed, on level track, of 14 miles per hour with eight seven-second stops per mile. The trackless trolley as far as acceleration, etc., are concerned is equally good. The gas bus, because of its limited power supply, and, if it is of the mechanical type, the necessity for shifting gears, is definitely slower than either of the other two; particularly if the number of stops per mile is large. This is one of the factors that makes the gas bus better suited to lines of light traffic, where the number of stops will be low.

The gas bus has a considerable advantage over both the other vehicles, in that, because it does have its own power plant, its route is not restricted to that of an overhead trolley. In times of emergency or even under normal[2] conditions this may be a very valuable asset. The self-contained power plant also makes possible both local and limited or express service on the same street without additional complications or investment. This double service is also made possible with the trackless trolley by use of either an auxiliary turnout in the overhead at the overtaking point, or of double overhead; either equipment requiring some additional investment. With street cars it is not feasible to operate both local and express service on the same street.

SECOND, ATTRACTIVE PROPERTIES OF VEHICLE

The private automobile has made the public more critical than formerly of its transit vehicles. In order to attract patronage the vehicle used should be comfortable to ride in and reasonably quiet in operation, and should be convenient to board and alight from.

Comfort and Quiet. In all of the new vehicles, regardless of type, much more attention is now being given to comfort and quiet. Seats are upholstered, and by an ingenious use of rubber in both running gears and body, the noise has been greatly reduced and the riding comfort improved.

Convenience. Because of curb loading, in convenience of ingress and egress, the advantage is very much in favor of the rubber-tired vehicles. The principal disadvantage of curb loading is that it may necessitate establishment of loading zones at the more important points, especially in business areas. To be effective, these zones must be kept clear of parked automobiles, so that the transit vehicle may draw in to the curb to pick up or discharge passengers.

THIRD, COST

In general, operating costs vary with both the size and kind of vehicle. For a given type, the operating cost per vehicle mile is less for a small conveyance than for a large one, but the cost per passenger mile is just the reverse. For a unit of given size, the gas bus requires the smallest capital investment, but has the highest operating cost (exclusive of interest and depreciation) of the three. Consequently it is best suited to lines of light traffic where the higher operating cost per mile is more than compensated for by the lower fixed charges on the smaller investment required. Hence, at light traffic volumes it yields a larger net return, with better headways and a smaller capital investment than would be possible with either the trackless trolley or the street car. The street car is best suited to very heavy mass transportation, where the traffic is heavy enough to require a large unit and is able to support the charges on the extra investment in track. Hence, with very heavy traffic, the street car, because of its larger size and lower operating cost per passenger mile, yields a greater net return, with entirely acceptable headways, than would be possible with either the trackless trolley or the gas bus, and this in spite of the large investment required for the track. The trackless trolley is intermediate between the other two, both in operating cost and investment.

As in any other business, in order for a transit system to continue as a going concern, its income must exceed, by a reasonable margin, its expenditures. Unfortunately, this has not been the case in the transit industry, as a whole, for many years.

---

[1] For all numbered references, see list at end of paper.

Two methods for remedying this deficiency have been tried. The first is to increase the income by increasing the rate of fare; the second is to raise the net income by improving the service so as to attract more patronage, at the same time reducing the cost of operation per passenger.

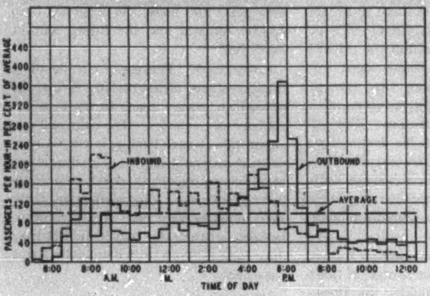

Figure 1. Typical curve of passengers per hour as a function of the time of day

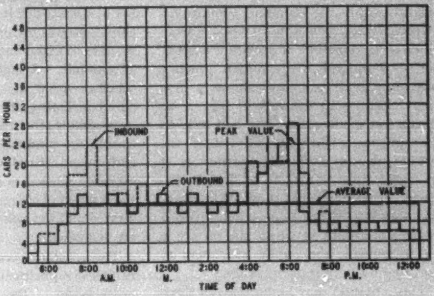

Figure 2. Typical daily car-demand curves

The efforts to increase the income by increasing the rate of fare have not been uniformly successful; in fact, in some cases where fares have been increased the resulting decrease in traffic has very largely offset the effect of the fare increase.

The second method, that of increasing the net return by improving the service, is much to be preferred. The most effective way of improving the service, and at the same time holding down costs, is to modernize the system by replacing old equipment with new vehicles properly chosen to fit the traffic conditions of each individual line.

So far as the author is aware, in all cases where a well-planned modernization program has been put into effect, the results have been better than were anticipated.[3-6] In addition to operating at reduced cost, the new vehicles have won and held increases in traffic that in many instances were truly remarkable.[2,7-10]

Factors That Determine the Choice of Vehicle

The foregoing discussion indicates that many factors influence the choice of vehicle in a given case. These may be classified roughly into two groups; first, those that have to do with the psychological appeal of the vehicle and, second, the economic factors.

The psychological or human elements of the problem are quite difficult or impossible to determine quantitatively and their relative importance in a given case is largely a matter of opinion or personal preference. For this reason no attempt has been made to determine which vehicle will have the greatest popular appeal but rather attention has been confined to the purely economic elements involved. Therefore, in what follows it is assumed that for equal headways the different vehicles are all equally capable of attracting patrons.

ECONOMIC CONSIDERATIONS

In determining the best vehicle with which to modernize a given line, three factors are of primary importance. These are, first, the net return; that is, the excess of income over total operating expenses; second, the possible headways; and third, the investment required.

The first is important because it determines the most economical vehicle to use. The second is important because it fixes the frequency of service and therefore, from the patron's viewpoint, largely the quality of the service rendered. The third is important because it determines the amount of new capital that must be provided.

For each kind and size of vehicle the net return, the headway, and the required investment all vary with the traffic to be handled. In a given case, the vehicle selected will normally be the one that can be operated most economically for the traffic existing. There are, however, exceptions to this rule. Sometimes, particularly with lines of light traffic, the most economical vehicle would require headways too large to give reasonably good service. In that case a smaller vehicle, operated with shorter headways, is desirable even at some sacrifice in the net return. Other exceptions may be found. For instance, the need to limit the number of types and sizes of vehicles on the system may result in choice of a vehicle other than the one that will give the best economy.

The reader has probably surmised that the problem of selecting the proper vehicle involves individual study of each line. This is the case particularly if an accurate forecast of the probable net return with the new equipment is to be obtained. However, as was noted previously, each vehicle has a certain volume range of traffic over which it is most economical. If this is known beforehand, then the problem of selection is greatly simplified.

Basic Data. Before the most economical traffic density range is determined for each type of vehicle the basic data must be established on which the solution of the problem depends.

The following general data were assumed to apply to all vehicles alike (the basis for each assumption is discussed in greater detail below): average schedule speed, 13 miles per hour; interest rate, five per cent; average fare, six cents; and duration of service, 19$^1/_2$ hours per day. Additional data applicable to specific vehicles are given in table I.

These data were derived from various sources. The average schedule speed of 13 miles per hour was estimated. As was mentioned before, the PCC car is designed to have a schedule speed of 14 miles per hour, with eight seven-second stops per mile. The trackless trolley is equally fast and modern busses could probably do as well in any service in which they would likely be used.

This value is probably high for dense traffic but it should approximate average conditions fairly closely. Admittedly, schedule speeds vary on different lines, but in general on a given line the schedule speed will be very nearly the same regardless of vehicle type.

The interest rate is taken at five per cent, as being approximately average. A low rate would be more favorable to those vehicles that require large capital investments.

The average fare of six cents is probably too low for the country as a whole. Its value would not affect the region of best economy in any case, although it would have a very decided effect on the net return. Consequently the comparison, as between vehicles, is the same regardless of the fare. The value of six cents was assumed because it is almost exactly the average fare, including transfers, etc., for the Seattle Municipal Railway System.

An allowance of ten per cent of the vehicles required on the peak was made for spares. This favors the gas busses slightly for, generallyspeaking, the availability of the electric vehicles is better than that of gas units.

The data listed in table I were also drawn from several sources. The values for vehicle-unit costs (column 2 of table I) were taken in part from manufacturers' bid prices, in part from published prices, or were estimated in those cases where information was not available from either. To determine accurate unit-cost data for the gas busses is particularly difficult because of the wide variations in specifications and manufacture for busses nominally of the same passenger capacity.

Depreciation. The life of new street cars is taken as 20 years; that of the trackless trolley as 10 years. These assumptions are close to the usual practice with regard to these vehicles. Except where stated otherwise, the useful life for the 30- and 40-passenger gas busses is taken as $6^2/_3$ years. For the 22-passenger gas bus, because of its generally cheaper construction, a useful life of 3 years is assumed. Practice with regard to depreciating gas busses varies considerably with different operating companies, the useful life assumed generally varying between 5 and 10 years.

As a matter of fact, any of these vehicles can be maintained almost indefinitely. Some street cars, still in operation, are more than 35 years old; similarly, trackless trolleys will last more than 10 years, and gas busses more than $6^2/_3$ years. In fact, the average age of the gas busses now in use in this country is estimated to be over 10 years. But few people nowadays want to keep a street car 35 years. Neither will they want to keep a trackless trolley or a gas bus more than a reasonable length of time. From a practical standpoint, if a vehicle is kept in service too long, operating costs go up, and generally patronage goes down. Modern advertising has taught the public to expect new models in its transit vehicles as well as in its private automobiles.

The assumed life of $6^2/_3$ years is undoubtedly very conservative for busses of good manufacture. Of course, if the depreciation rate were reduced these vehicles would make a somewhat better showing. Similarly, if the depreciation rate for the street cars were increased it would suffer by comparison. The effect of changing the depreciation rate is shown more in detail, for the case of the 22-passenger gas bus, in figures 20 and 21.

Use of a vehicle having a shorter life is not without advantage. For example, suppose that the condition of traffic and track on a given street-car line were such that the line could be modernized at practically equal cost with either new street cars or gas busses. Equal cost means that if new street cars are used they must be kept in service for 20 years in order to recover the investment. If on the other hand, the line be modernized by using, say, 40-passenger gas busses, which are "written off" the books in $6^2/_3$ years, the line could have new equipment of the same or better type, should better-type equipment be then available, every $6^2/_3$ years. Or if at the end of the depreciation period the equipment had some useful life remaining it could be kept in service until completely worn out. Each time new equipment is put into service the result will normally be an increase in traffic, for which the type of vehicle should have credit.

Another disadvantage of a long-term program is that frequently community development makes necessary improvements, such as grade changes, repairing operations, etc., which were not taken into account in the original calculations.

The depreciation rate on the new investment in track, which is assumed also to include any necessary rehabilitation of the overhead, has been taken at four per cent. The assumption is that street-car operation will be continued indefinitely. If street-car operation is to be discontinued at the end of the usual life (20 years) of the new rolling stock, the depreciation rate on the new investment in track will properly be five instead of four per cent. The depreciation rate on the overhead for the trackless trolley has been assumed to be five per cent. The above procedure is more than fair to the street car.

No attempt has been made to depreciate the old investment in track or overhead on the ground that if present street cars are to be replaced, for example by gas busses, all the present investment in track will have to be retired. Salvage value is ignored in all cases. Also no allowance is made for removing the old rails from the street in case rail operation is abandoned. Probably the most satisfactory method of handling this problem is to cover the old rails with asphalt until repaving becomes necessary, at which time they can be removed inexpensively.

Operating Costs. The operating costs per vehicle mile given in table I are estimates. Some of the values check reasonably well with recently published data[11] for similar vehicles. In different

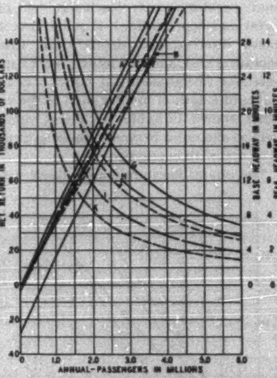

Figure 3. **Net return and headway versus annual passengers, three-mile line, L=0.9, m=2**

A—Net return, PCC car, with no track rehabilitation cost
B—Net return, PCC car, with track at $100,000 per double-track mile
C—Net return, 44-passenger trackless trolley
D—Net return, 30-passenger trackless trolley
E—Net return, 40-passenger gas bus
F—Net return, 22-passenger gas bus
G—Headway, PCC car
H—Headway, 44-passenger trackless trolley
I—Headway, 30-passenger trackless trolley
J—Headway, 40-passenger gas bus
K—Headway, 22-passenger gas bus

parts of the country operating costs vary considerably, owing primarily to differences in wages, and in fuel and power costs. The values quoted are as nearly average as could be determined from the data available. In sections where electric energy is expensive, the operating costs for the electric vehicles will be more than the figures quoted in table I, while cheap gasoline will tend to lower those for the gas busses.

Another cost, difficult to determine in a general study of this kind, is taxes. The difficulty arises from the fact that there are almost as many and varied methods of assessing taxes against transit systems as there are transit systems. In a specific case the taxes will be known and can be taken into account. The fact that taxes are herein neglected will not, in general, greatly alter the region of best economy for the various vehicles, because taxes would affect all to almost the same degree.

Determination of the Most Economical Traffic-Volume Range for Each Vehicle. From the basic data, previously established, values of annual-passengers, annual-vehicle miles, annual-revenue, annual-operating cost (exclusive of interest and depreciation), required investment, interest, and depreciation, total operating cost, and net return, were computed for various assumed values of headway and length of line for each of the vehicles shown in table I. These values were so chosen as to cover the usual range to be met with in practice.

The quantities enumerated above may be calculated individually; or, more conveniently, particularly if only the net return is required, the various relationships can be put into a single equation, thus:

Table I

Type of Vehicle	Unit Cost of Vehicle (Dollars)	Vehicle Seating Capacity	Depreciation (Per Cent)			*Average Operating Cost (Cents Per Mile)
			Vehicles	Track	Overhead	
54-passenger PCC car	15,000	54	5	4	4	23.0
44-passenger trackless trolley	13,000	44	10	None	5	18.5
30-passenger trackless trolley	9,500	30	10	None	5	15.5
40-passenger gas bus	10,000	40	15	None	None	21.0
22-passenger gas bus	2,200	22	$33^1/_3$	None	None	14.25

* Excluding interest and depreciation.

$$R=AF-365k_1lt_0C_a-\frac{k_3PUlC_p}{V}-\frac{k_4lT}{2} \quad (1)$$

or

$$R=\frac{alF}{2}-365k_1lt_0C_a-\frac{k_3PUlC_p}{V}-\frac{k_4lT}{2} \quad (2)$$

or again

$$R=730LFSt_0C_a-365k_1lt_0C_a-\frac{k_3PUlmC_a}{V}-\frac{k_4lT}{2} \quad (3)$$

where

R = net return
P = 1.1 = ratio of total vehicles, including spares to the vehicle required on the peak
F = average fare in dollars = 0.06
t_0 = hours of service per day = 19.5
V = schedule speed = 13 miles per hour
U = unit cost of vehicle in dollars
k_1 = average operating cost per vehicle-mile in dollars, exclusive of interest and depreciation
k_3 = interest rate plus depreciation rate (in decimal) on vehicles
k_4 = interest rate plus depreciation rate (in decimal) on track and overhead (street car) or on overhead (trackless trolley)
h = headway in minutes
C_p = cars per hour during peak period
C_a = average cars per hour = average ordinate of car-demand curve
T = cost of rehabilitating track and overhead, for the street car, or cost of overhead for the trackless trolley, in dollars per double track mile (DTM)
S = seating capacity of vehicle
L = average loading of vehicle, that is, the ratio of the average number of passengers per trip to the vehicle seating capacity, in decimals
l = round-trip length of line in miles
A = total annual passengers
a = total annual passengers per route mile $=2A/l$
m = ratio (in decimal) of the cars per hour on the peak (C_p) to the average, or base, cars per hour (C_a); is also equal to the ratio of the average, or base, headway to the peak headway

The first term, AF, is the annual gross income; the second term, $365k_1lt_0C_a$, is the yearly operating cost exclusive of

interest and depreciation; the third term, k_3PUlC_p/V, is the interest and depreciation on the vehicles alone; while the last term $k_4JT/2$, is the interest and depreciation on the new investment in track and overhead, if the street car is under consideration, or the overhead in case of the trackless trolley.

Equation 1 assumes the same schedule every day, including Sundays and holidays. The error introduced only slightly alters the region of best economy for it affects all vehicles to much the same degree. This error could be eliminated by computing separately the annual vehicle-miles for weekdays and for Sundays and holidays, then adding. The additional accuracy obtained would hardly be worth while for the present purpose.

Figure 1 shows typical curves of passengers per hour as a function of the time of day for an existing street-car line. Figure 2 shows the corresponding curves of cars per hour with a 44-passenger vehicle, plotted to the same abscissas. The curves of both figures 1 and 2 were plotted from data taken during a traffic count on this line. For each size of vehicle there are vehicle-demand curves corresponding to those of figure 2.

The connection between the curves of figures 1 and 2, and equations 1, 2, and 3, may be shown as follows: the second term of equation 1 shows that the operating cost is proportional to the quantity t_0C_a, the area under the car-demand curve of figure 2. The daily vehicle-miles, and consequently the operating cost also, are dependent on the length of the line and on the area under the car-demand curve, not upon the shape of this curve, unless of course changing the shape of the curve will alter the average cost of operation per vehicle-mile. The third term of equation 1 contains the term C_p. This is the peak value, averaged over the time of a round trip, of the car-demand curve.

The total number of daily passengers is the area under the passenger-time curve. The total of annual passengers (A) must equal that of passengers per vehicle-mile multiplied by the annual vehicle-miles, or

$$A = \frac{\text{(average vehicle-loading)(seating capacity)}\\ \text{(annual-vehicle-miles)}}{\text{(route-miles of line, one way)}}$$

hence

$$A = \frac{2LS}{l}(365lt_0C_a) = 730LSt_0C_a \qquad (4)$$

Equation 4 shows that for a given vehicle size and loading the annual-passenger total is also proportional to the area under the car-demand curve which is t_0C_a. If the relationship of equation 4 and also that of $C_p = mC_a$ is substituted into equation 1, equation 3 is obtained.

Results. The results of applying the above method of analysis are shown graphically in the following curves.

Figures 3 to 6 inclusive, show the relationship between net return and annual passengers for lines of varying length, assuming a constant average loading of 0.9 and a ratio of average to peak headway of two. In figure 3 are shown, in addition, curves of base and peak headway as a function of annual passengers for the different vehicles. Since the headway, for a given size of vehicle and number of annual passengers is independent of the length of line, headway curves are not shown in figures 4, 5, and 6, for they would be identical with those of figure 3.

Inspection of figures 3 to 6 inclusive reveals a number of interesting facts. For example, the curves show that, if the present track is in such good condition that it will require no more than normal

upkeep during the life (20 years) of the new rolling stock, it will be more economical to modernize with new street cars than with any other vehicle. If, on the other hand, the track must be rebuilt at a cost of $65,000[18] per double-track mile, which is about the minimum cost at which track in paved streets can be rebuilt, the 44-passenger trackless trolley is more economical than the street car, up to a value of annual passengers well beyond the range of the curves. This point will be discussed more in detail later.

The curves also show that, for values of annual passengers below approximately 2,000,000 passengers per year, the headways with any of the three larger vehicles will be very poor indeed, unless these vehicles are operated at a smaller average load than 90 per cent, which would in turn reduce the net return. When the annual load falls to 1,000,000 passengers or less, the small (22-passenger) bus is the only vehicle that can be run with a reasonably good headway. This point will also be discussed more completely presently.

Comparison of figure 3 with figure 5 shows that the net return, for a given number of annual passengers, is greater for the three-mile than for the seven-mile line. This result is to be expected, since for the same number of annual passengers, other factors remaining the same, the passengers per vehicle-mile must be larger on the three-mile than on the seven-mile line. But in order to have the same number of annual passengers, the annual-passengers per route-mile must be greater on the short line. This relationship in turn requires that the population density, assuming equal riding per unit of population, must be greater on the short line. A more interesting comparison is obtained, as between lines of different lengths, if the annual-passengers per route-mile, instead of annual passengers, is made the independent variable.

Accordingly in figures 7 to 10 inclusive, are shown curves of net return as a function of annual-passengers per route-mile. The vehicles used, and the other pertinent data, are the same as for figures 3 to 6 inclusive. As will be noted, while the latter curves have essentially the same shape as the former, the relative values have considerably changed. The net return for a given passenger density is greater for lines of intermediate length than for either very long or very short ones. This result immediately leads one to suppose that for a given traffic density there is a definite length of line that will give a maximum net return. Inspection of equation 2 and of the curves of figure 11 confirms this supposition.

In figure 11 are shown curves of net return versus length of line, for the same vehicles as before, for a constant traffic density of 1,000,000 passengers per route-mile per year. For each vehicle there is one definite length of line that will yield the greatest return. This optimum length is greater, the lower the total cost of operation per passenger mile. The curves also show that each vehicle has a maximum length of line beyond which a deficit will appear. This finding agrees with operating experience that long lines are relatively unprofitable unless local traffic is sufficient to keep the passengers per vehicle mile at a profitable level.

In figure 12 are shown curves of headway versus traffic density for 54-, 44-,

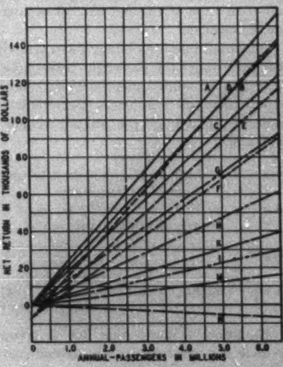

Figure 13. Curves of net return versus annual passengers for different values of the ratio m; seven-mile line, $L = 0.9$

PCC car:
A—$m = 1$ B—$m = 2$ C—$m = 3$

44-passenger trackless trolley:
D—$m = 1$ E—$m = 2$ F—$m = 3$

40-passenger gas bus:
G—$m = 1$ H—$m = 2$ I—$m = 3$

22-passenger gas bus:
K—$m = 1$ M—$m = 2$ N—$m = 3$

and 22-passenger vehicles, for three-, five-, six-, and nine-mile lines. These curves show that for a given number of passengers per route mile and size of vehicle, the longer the line the better the headways will be. This finding agrees with operating experience. As is common knowledge, it is difficult to give close headways on short lines with any but small vehicles, while on long lines it is relatively easy to provide good headways even with large units.

Effect on Net Return of Changes in Ratio of Peak to Average Number of Vehicles per Hour. In figures 3 to 11 inclusive, the ratio (m) of peak to base cars per hour was assumed to be two, which is almost the exact value for the line of figures 1 and 2. The value of m is a measure of the peak service necessary in terms of the average, and therefore of the required investment in vehicles. For this reason the net return will depend, to a considerable degree, upon the magnitude of m. This will be particularly the case with equipments that have a high first cost or a high depreciation rate.

On light lines where, for the sake of maintaining certain minimum standards of service, considerably better headways are usually provided during the off-peak period than the traffic warrants, the value of m may be less than two. On the other hand, on certain routes serving highly industrialized centers the value may be greater than three.

F—Gas bus at 21 cents per mile
G—Gas bus at 20 cents per mile

Figure 13 shows the variation in net return with annual passengers for different values of m, so chosen as to cover the range likely to be met with in practice. This figure also shows that the region of best economy for each vehicle also varies with the value of m. As predicted above, the advantage is in favor of the vehicles of low cost and low depreciation rate.

In order to show the region of best economy for the PCC car, the 44-passenger trackless trolley, and the 40-passenger gas bus, the curves of figure 14 were computed. Any individual curve is the boundary line between the regions of maximum economy, under the stated conditions, for the two vehicles to which it refers. To make this point more clear suppose, for example, that a new investment of $40,000 per double-track mile will be needed to rehabilitate the track on a certain existing street-car line that is to be modernized. If the point corresponding to the annual traffic and the value of m for this line is located above and to the right of curve C of figure 14, the street car will give the more economical service; but if the point falls below and to the left of curve C the trackless trolley will give a larger net return. This conclusion does not give the trackless trolley credit for the fact that, because the headways with it will be approximately 22 per cent better than with the street car, it will therefore tend to attract a greater traffic increase.

To illustrate further the use of the curves of figure 14, the line of figure 2 is assumed, for which m is slightly greater than two. This line has an annual traffic of approximately 6,500,000 passengers. Curve C shows that, if a new investment of less than $40,000 per double-track mile is required to rehabilitate the track on this line, the street car will be the more economical; but if the new investment in track must exceed $40,000 per double-track mile, the 44-passenger trackless trolley will give service that is more economical and at the same time more frequent, by approximately 22 per cent.

Figure 15 shows the amount that may be spent in rehabilitating the street-car tracks for equal return with the 44-passenger trackless trolley for different values of m. For example, assume a line that has an annual traffic of 8,000,000 passengers and a value of m equal to three. Curve C of figure 15 shows that if track rehabilitation required an expenditure of less than approximately $64,000 per double-track mile, the street car would be the more economical, but that if the expenditure required exceeded that amount the trackless trolley would be the more economical as well as giving more frequent service.

Importance of Average Loading. In figures 3 to 15 inclusive, the average passengers per vehicle was maintained constant at 0.9 or 90 per cent of the vehicle-seating capacity. Equation 3 shows that a small change in the value of L, the average vehicle loading, will produce a relatively large effect on the net return. This relationship is shown by the curves of figures 16 and 17. The curves show that, for the three-mile line, a 20-per-cent decrease in the value of L (which is another way of saying a 20-per-cent decrease in passengers per vehicle-mile) produces a decrease in the net return that varies from approximately 26 per cent, for the street cars, to about 32 per cent for the 22-passenger bus; while for the seven-mile line the same percentage of decrease in L produces a decrease in the net return that varies between approximately 41 per cent, for the street car, and about 147 per cent for the 22-passenger gas bus. This shows the great importance—one might almost say the

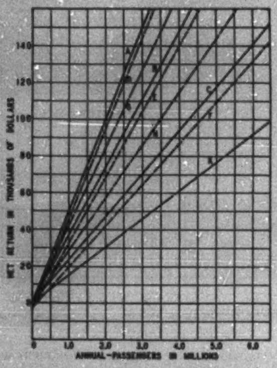

Figure 16. Net return as a function of annual passengers at constant values of vehicle loading, three-mile line, m = 2

PCC car, no track rehabilitation:
A—*L* = 1.0 *B*—*L* = 0.8 *C*—*L* = 0.6
44-passenger trackless trolley:
D—*L* = 1.0 *E*—*L* = 0.8 *F*—*L* = 0.6
22-passenger gas bus:
G—*L* = 1.0 *H*—*L* = 0.8 *K*—*L* = 0.6

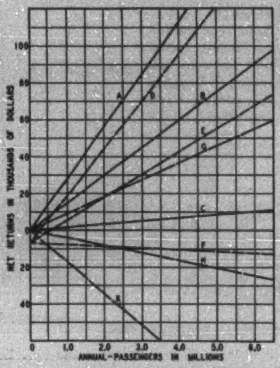

Figure 17. Net return as a function of annual passengers at constant values of vehicle loading, seven-mile line, m = 2

PCC car, no track rehabilitation:
A—*L* = 1.0 *B*—*L* = 0.8 *C*—*L* = 0.6
44-passenger trackless trolley:
D—*L* = 1.0 *E*—*L* = 0.8 *F*—*L* = 0.6
22-passenger gas bus:
G—*L* = 1.0 *H*—*L* = 0.8 *K*—*L* = 0.6

necessity—of keeping the average loading high, particularly on long lines with vehicles that have relatively high operating costs per passenger mile.

This more than proportional change in net return with a given change in loading, is one factor that makes possible, in certain cases—principally with light lines—replacement of a larger vehicle with one of less capacity, thus giving a more attractive headway, and still operating at a profit. During periods of light load, with the same or better headway, the small vehicle will be more nearly loaded, thus raising the value of the average passengers-per-vehicle-mile.

The factors involved can perhaps be most conveniently illustrated by use of an actual example. Figure 18 shows the relationship between passengers-per-hour and the time of day for an existing 6.9-mile street-car line having an annual traffic of approximately 1,745,000 passengers. It is proposed to modernize this line, using the vehicle that will give the best all-around performance. Figure 5 indicates that this line can probably be operated most economically with a 44-passenger trackless trolley, unless the track is in such good condition that an investment of approximately $25,000 per double-track mile will restore it to normal; in this case the PCC car would be the most economical. But reference to the headway curves of figure 3, which also apply to figure 5, indicates that the possible headways, with either the 44-passenger trackless trolley or the PCC car, will not be particularly good, certainly not good enough to attract any considerable amount of additional patronage. This result immediately suggests the desirability of using a smaller vehicle if such a course can be justified economically.

Figure 19 shows vehicle-demand curves for units of the several sizes made up from the traffic curves of figure 18. For the most part the curves of figure 19 provide very liberal schedules. In no case would passengers have to stand during the midday period. This insurance is highly desirable if increased riding is to be encouraged, particularly during the off-peak period. Also the maximum headway was set at 20 minutes, excepting only after 11:00 p.m. After 11 the headway is 30 minutes. The same schedule was assumed for both directions of travel.

Because of the large difference in traffic in the two directions on this line it is difficult to keep the average vehicle loading at a good figure without at the same time forcing some passengers to stand, in the heavy direction of travel, even during the off-peak period. The operating results to be expected for the various conditions and vehicle sizes are set out in table II. Line 1 of table II shows the forecast for the PCC car, assuming an average track rehabilitation cost of $20,000 per double-track mile. If the required expenditure for track rehabilitation is greater than approximately $24,500 per double-track mile, the street car will incur a deficit.

Line 2 of table II shows the projected results for the 44-passenger trackless trolley, with present traffic and a vehicle-demand as shown by curve *C* of figure 19. By decreasing the headways after 7:00 p.m. to values more nearly in line with the traffic after that time, and one or two other minor adjustments in schedule, the $899 deficit may be converted into a net gain of $6,556.

Line 4 shows the results to be expected if the new equipment is able to attract a ten-per-cent increase in traffic. This item shows very strikingly the improved results with even a very moderate gain in patronage. Items 5, 6, and 7 are the same as items 2, 3, and 4, except that they apply to the 40-passenger gas bus. Curve *C* is liberal enough so that a ten-per-cent, and better, increase in traffic can be accommodated without an increase in facilities.

Items 8 and 9 are for the 30-passenger trackless trolley. The first is for present traffic; the second assumes an increase in traffic of 15 per cent (15 per cent is assumed because of the better headways offered by the smaller vehicle). With the 15-per-cent increase in patronage it would be desirable to augment the facilities, as shown by curve *B*. The net return, with the 30-passenger trackless trolley and the 15-per-cent increase in traffic, is $10,502 as compared with $9,571 for the 44-passenger trackless trolley with a 10-per-cent increase in traffic. In addition, the headways with the smaller vehicle are much better and also, owing to fewer stops with it, its schedule speed would be higher.

A 30-passenger gas bus that cost $8,000 per unit and had a useful life of eight years (not 6$^{2}/_{3}$ as assumed for the 40-passenger gas bus in figures 3 to 17 inclusive) would have to have an operating cost of not over 16.87 cents per mile, in order to equal the performance of the 30-passenger trackless trolley. Whether the gas bus could be operated for only 1.37 cents more per mile than the trackless trolley is doubtful. However, the gas bus would have a decided advantage, in that express service could be provided during the peak period without additional complication or expense; something not possible with the trackless trolley.

The small or 22-passenger gas bus, at 14.25 cents per vehicle-mile, shows a deficit on this line, unless the loading is kept

Table II

Item Number	Vehicle	Schedule Curve From Figure 19	Annual Passengers	Headway in Minutes: Peak	Headway in Minutes: Mid-day	Headway in Minutes: Evening Early	Headway in Minutes: Evening Late	Average Loading in Per Cent of Vehicle Seating Capacity	Passengers Per Vechicle Mile	Annual Miles Per Vehicle	Net Return in Dollars	Remarks

10	30-passenger gas bus	*B*	2,006,750	4.6	10	20	30	86.5	3.75	27,701	4,472	15 per cent traffic increase. 30-passenger gas bus at $8,000 each. Eight-year life. Operating cost at 18 cents per bus mile

high. To accomplish this, passengers must stand in the heavy direction of travel, even during part of the midday period. This is very undesirable if off-peak riding is to be encouraged. The traffic on this line is too large for the most economical operation of the 22-passenger unit.

Undoubtedly the 30-passenger trackless trolley is the proper vehicle to use on this line, unless the cost figures for the 30-passenger gas bus are more favorable than is indicated above.

The above analysis shows very clearly the comparatively large gains in net return due to even small increases in patronage. Therein lies one of the opportunities of modernization. Experience has shown that where service is improved, increased riding results. The best way to improve service, particularly on light lines, is to decrease the headways by substituting smaller, faster, more economical units, operated on closer schedules. In many cases where this has been tried, the results[3] obtained have been remarkable. Lines that were otherwise unprofitable have been converted into money-makers. This is the field for the small bus, and accounts in part for its growing popularity.

The above analysis also shows the importance of adjusting schedules so as to keep the vehicle loading as high as possible, consistent with good service. It shows too what is meant by "operating the smallest vehicle possible within the economic limitations".

Operating Cost. As was mentioned previously, the operating cost, exclusive of interest and depreciation, is the most important of the items of expense in the operation of a transit line. Its importance is indicated by the curves of figures 20 and 21. These show, first of all, that on a short line the operating cost is relatively unimportant. For example, figure 20 shows that for the three-mile line, if the operating cost of the 22-passenger gas bus is reduced from 14.25 to 11 cents per mile, a change of approximately 23 per cent, the corresponding variation in the net return will be slightly less than 13 per cent.

For a long line the conditions are very different. Even small changes in operating cost produce relatively large variations in the net return. This is particularly true of the small units. These statements can be verified by reference to figure 21, which shows that, for a seven-mile line, if the operating cost of the 22-passenger bus varies over the same range of 23 per cent as assumed above, the corresponding change in the net return will be about 72 per cent instead of 13.

In the curves of figures 3 to 10 inclusive,

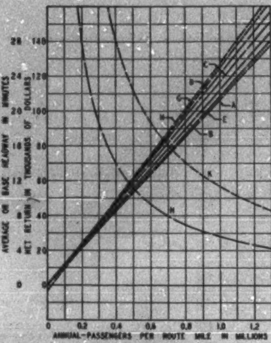

Figure 20. Net return versus passenger density for the small bus; three-mile line, L = 0.9, m = 2

22-passenger gas bus, three-year life; operating cost per mile at:
A—$14\frac{1}{4}$ cents C—12 cents
B—13 cents D—11 cents

22-passenger gas bus, four-year life:
E—Operating cost $14\frac{1}{4}$ cents per mile

44-passenger trackless trolley, ten-year life; operating cost per mile at:
G—$18\frac{1}{2}$ cents H—$17\frac{1}{2}$ cents

K—Headway, 44-passenger trackless trolley
N—Headway, 22-passenger gas bus

the operating cost of the small bus is taken as 14.25 cents per bus mile. This value should be conservative for this unit; in fact some transit companies[13] have operated it for approximately 11.75 cents per mile, exclusive of taxes, interest, and depreciation.

The importance of a low operating cost is strikingly illustrated by the curves of figure 21. This figure shows that an increase in the normal life of this vehicle from three years to four years has about the same effect on the net income as a decrease in the operating cost of one-half cent per mile. Also, it shows that if the 22-passenger gas bus could be operated for ten cents per mile it would be more economical than the 44-passenger trackless trolley at 18.5 cents per mile, up to an annual load of approximately 5,000,000 passengers.

If this vehicle could be operated at such a low figure its usefulness would be very greatly increased. For instance, service would be possible on lines of much lighter traffic than is now economical. Of course, a decrease in operating expense is equally important with any of the other vehicles. The small bus was used for illustration because the results with it are perhaps more striking.

The fact was mentioned previously that to keep equipment in service too long is unprofitable. The small bus is more likely to fall under this rule than any other vehicle. For the conditions shown in figures 20 and 21 the average annual mileage per vehicle amounts to approximately 42,000. On the basis of three years of life, the annual interest and depreciation per unit amounts, at $2,200 each, to $843. If at any time the difference in operating cost per mile between the old and a new bus amounts to as much as two cents per mile, the saving in operating cost will be enough to pay the interest and depreciation on a new vehicle.

A much more important consideration is that patronage falls off if the vehicle is kept in service too long. As was indicated previously, only a very small drop in patronage would be required to reduce the net return by an amount equal to the carrying charges on a new vehicle. Obviously it is unprofitable to keep old equipment in service too long, particularly since new equipment generally brings an increase in riding. With the more expensive equipments obsolescence and decreased riding would make the change desirable long before increased operating costs would have a very great effect.

Capital Costs. In figure 22 is shown for a representative case the amount of new investment required for varying values of traffic density. The curves show that the small bus requires by far the least investment of any of the vehicles considered. For the others the investment required, in vehicles alone, is not greatly different; but when the cost of the overhead for trackless trolley, and of the track and overhead for the street car, are added, the required investment, especially for the street car, may be greatly increased.

Conclusions

The first conclusion to be drawn from the previous discussion is that if the present track has a useful life remaining equal to that of new rolling stock, the PCC car is the most economical vehicle to use in modernizing an existing line; if in addition the volume of traffic is sufficient to warrant a reasonable frequency of service with so large a unit, the PCC car will also probably be the best vehicle to use.

If on the other hand track rehabilitation is necessary, then—the choice depending on the expenditure required for this work and on the traffic density—either the trackless trolley or the gas bus may be more economical as well as offering more frequent service.

Figure 14 shows that, if the track must be completely rebuilt at a cost of approximately $60,000 per double-track mile, the 44-passenger trackless trolley is more economical than the PCC car up to values of annual passengers of approximately 5,500,000, 7,000,000, and 11,000,000, corresponding to values of *m* of four, three, and two respectively.

Five and one-half million passengers per year is fairly heavy traffic. The heaviest line in Seattle has an annual load of approximately 6,500,000 passengers with a value of *m* equal to practically two. (The curves of figures 1 and 2 are for this line.)

In a given case the above conclusions may be modified by a full consideration of the psychological factors involved. The quantitative relations may also be altered if the various costs are appreciably different from the values used above.

The principal advantage of the street car is its ability to handle heavy traffic, with sharp peak loads. In this connection it should be mentioned that at about the time this study was nearing completion one of the vehicle manufacturers announced a new rubber-tired vehicle,[14,15] available either as a trackless trolley or as a Diesel-electric bus, of practically street-car capacity. As no cost data were available on this vehicle it is not included in this report. But if, as would be expected, first cost, operating cost, depreciation, etc., for this unit are in line with corresponding costs for the smaller trackless trolleys now in use, the curve for this vehicle could be expected to occupy a

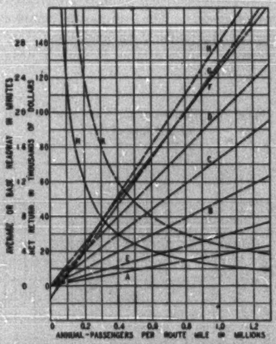

Figure 21. Net return versus passenger density for the small bus; seven-mile line, L = 0.9, m = 2

F—22-passenger gas bus, three year life operating cost per mile at ten cents

Other curve designations same as in figure 20 place, in figures 3 to 13 inclusive, very close to the curve for the PCC car without track-rehabilitation cost. If this should prove to be the case, and if the operating characteristics of the new vehicle are also satisfactory, the street car has a worthy competitor in the heavy-traffic field.

Unless some new development should bring much cheaper track, or a marked drop in interest rates occurs, it is probable that, as present tracks wear out, economic pressure will force the gradual retirement of the rail car from all except the very heaviest surface lines.

The future role of the trackless trolley and of the gas bus is not quite so clear, but for the near future the backbone of the transit system appears to be the trackless trolley, with gas busses on the lighter lines. Figure 14 shows that with an operating cost of 18$^1/_3$ cents per mile for the 44-passenger trackless trolley and of 21 cents per bus mile for the 40-passenger gas bus, the trackless trolley is the more economical for all values of traffic greater than approximately 800,000 passengers per annum. If the operating cost of the gas bus can be reduced to 20 cents per mile the point of equal return is raised to approximately 2,000,000 passengers per year. Evidently the position of the line separating the regions of best economy for these two vehicles is very sensitive to small changes in the relative operating costs. The relative position of these two vehicles could be expected to vary considerably in different sections of the country due to differences in fuel and power costs.

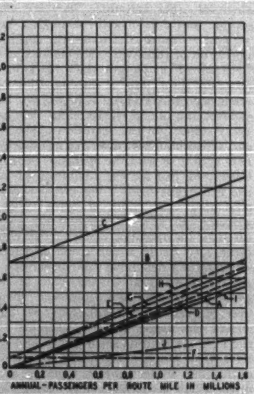

Figure 22. Investment required versus traffic density; seven-mile line, L = 0.9, m = 2

J—22-passenger gas bus

Undoubtedly the future will bring additional improvements in both vehicles that will reduce operating costs. The Diesel-electric is a step in this direction for the self-propelled vehicle. Whether the Diesel-electric, or perhaps the Diesel with hydraulic transmission, will be able to partially or completely supplant the electric vehicles remains to be seen. One influence that will tend to prevent this replacement is the fact that the trend in power rates is steadily downward while that of gasoline and oil prices is up.

The previous discussion also shows the importance of good engineering and good management in a prospective modernization program, not alone in selecting the most suitable vehicle for each line, but also in adjusting schedules and maintaining service so that riding will be encouraged.

Discussion

G. M. Woods (nonmember; Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Professor Hoard's paper is a valuable document to those engineers who are faced with a decision as to the type of vehicle to use for particular transit conditions. The study of the problem from the patron's standpoint as well as the economic standpoint is particularly desirable. The ability to attract new patronage and, by merit, to retain it must be the primary objective of any transportation system. Frequently economies in operation have been carried too far, with the result that gross revenues have decreased more rapidly than operating expenses. Fortunately, the modern vehicles and equipment available are not only more attractive to the passengers but they also are more economical to operate than the older vehicles.

Care must be exercised in a study of this type to avoid drawing general conclusions from a specific example. All of the conditions surrounding any particular application must be carefully analyzed and the correct basic data determined. The paper points out the material effect on the "regions of best economy" of relatively minor changes in operating cost.

Not only must present conditions be considered but thought must be given to the future also. For instance the author assumes a useful life of 20 years for street cars, 10 years for trolley coaches, 6$^2/_3$ years for the larger motor busses, and 3 years for the 22-passenger busses. The price which must be paid for replacement vehicles at the end of 3, 6, or 10 years is unknown, although it is an important factor in long-term planning. As brought out in the paper the downward trend of power rates is in favor of electrically propelled vehicles.

L. C. Josephs, Jr. (Mack Manufacturing Corporation, Allentown, Pa.): Perhaps the most important factor in the choice of transportation equipment is the matter of merchandising and not engineering. There has perhaps been too much engineering in some places and not enough attention paid to the merchandising of transportation. The engineering side is apt to look on such factors as the cost of operation, without paying enough attention to the rather indefinite question of what makes people ride and how can more of them be made to ride.

In a general way, the engineering side of transportation equipment has to do more with the cost of operation, whereas the merchandising side of transportation has to do more with the question of gross income. Sometimes to get the optimum difference between income on one hand and operating expense on the other hand, it is necessary to do things that may seem wrong from a strictly engineering standpoint. That, however, is just what some of the railroads are doing on their modern streamlined trains, where more attention is being paid to showmanship and less to operating economies. Maybe in this present day it is necessary to use considerable showmanship to get the people to ride on the urban transit systems.

H. E. McWethy (Twin City Rapid Transit Company, Minneapolis, Minn.): In discussing this paper I would first like to commend Professor Hoard on the thoroughness with which he has handled the technical aspects of a complicated problem. It is not easy to condense in so short a paper all of the diversified factors which should be and must be given consideration in the determination of the most economical type of vehicle to serve efficiently and safely the requirements of the riding population of any given community. While it is evident throughout the paper that Professor Hoard has had in mind the application of his general solution to the needs of the city of Seattle, Wash., it is also evident that the principles which he has set forth and the manner of solving the problem has a rather universal application to the street-railway systems of the United States. It is no disparagement to the excellence of this paper to say that many of the principles set forth therein have been used by the transportation industry in one form or another in the solution of similar problems for a considerable number of years. This is the first time, however, that we have had the advantage of having these methods set forth as a coordinated whole amply illustrated by the use of graphs.

I presume that our local engineers in the Twin City area would be happy if in this discussion I could take the graphs and formulas presented by Professor Hoard and apply them to the operations of the local transportation system of Minneapolis and St. Paul and thus determine just what should be done with this system. Obviously in a short discussion such an accomplishment is impossible. However, without attempting to reach definite conclusions, I would like to leave certain thoughts for your consideration which came to me as I went over this paper attempting roughly to evaluate our own performance in the light of the methods of analysis proposed in this paper.

At the outset Professor Hoard's analysis gives little if any consideration to the economy of the continuation of equipment which is at present in use on a given system. He assumes that all existing equipment has reached the point where it is uneconomical to continue its use further and that the choice of the transportation industry lies only with the PCC car, the trolley bus, and the gasoline bus. So far as our own system is concerned, we believe that this conclusion as to existing equipment being obsolete for the purpose of solving our transportation problems is not entirely warranted. We have reason to believe that the newer types of equipment must prove themselves by demonstrated economies over the equipment at present in use. In our case unless the newer types of equipment can demonstrate a much greater attractiveness to the public than the equipment at present in use, thus increasing the riding habit materially, there can be little question, so far as our entire system is concerned, as to the net economy of the continuance of the existing equipment in service. Quite rightly, we believe, Professor Hoard dismisses the question of increased riding which would follow the adoption of the new equipment as controversial and a matter of individual opinion, and he assumes for the purpose of his analysis that no change in the riding habit would follow the adoption of a different type of vehicle.

Having reached this conclusion, the remainder of the problem lies in the decision as to whether or not it is more economical with present patronage to continue in operation existing equipment than to adopt one or more of the three types of equipment which are suggested by Professor Hoard.

To justify the increased fixed charges on new equipment purchased there must be quite a marked differential in performance between the old and the new equipment. This differential may take the form of increased speed, greater comfort and convenience of passengers, or lower maintenance costs. The need for the new type of equipment will be most apparent on those properties where this differential between the old and new equipment is greatest. On properties where the differential is least no justification for a change may exist. We feel that the equipment on our property offers a case in point. Certain it is that good economics would frown on the adoption of stream lines without perceptible increase in the comfort and convenience of passengers, and it seems also fundamentally true that to destroy useful remaining life of well-maintained equipment without securing in the new equipment increased benefits of equal or greater value would be likewise unsound. We feel at the present time that the only case where the adoption of a new vehicle is warranted on this system is where a large section of track and paving on an existing line is worn out and must be replaced. In such a case the adoption of a rubber-tired vehicle may be more economical than the continuance of existing rail service.

When we come to compare operating data experienced on this system with that assumed by Professor Hoard, we find on the whole that a close similarity exists. For instance, in table I of his paper he shows 23 cents per car-mile as the average operating cost (excluding depreciation) for the PCC car. The comparable figure on our system for 1938 was 21.8 cents. For our busses which average 26 passengers each, the annual operating cost, exclusive of depreciation, was 15.78 cents per bus-mile, which may be compared with 21 cents per bus-mile which he has used for a 40-passenger gas bus and 14.25 cents for a 22-passenger gas bus.

The average fare per passenger (including transfer passengers) which Professor Hoard assumed of 6 cents compares with the average railway fare on this system of 5.52 cents. (Our record indicates that the average fare per *revenue passenger only* in Seattle approximates 8.3 cents as compared with 7.75 cents, the average fare on this system per revenue passenger.)

Now just a word as to the transportation property which serves the Twin City area. The population served approximates 800,000. The number of street cars is 715, operated on 459 miles of track. These cars operate approximately 21,860,000 car-miles annually and haul in the neighborhood of 100,000,000 passengers annually. This railway operation is supplemented by the operation of 116 gasoline busses which operate approximately 3,800,000 miles annually and carry approximately 4,500,000 revenue passengers. Of the 715 railway cars, all but 35 are unusually heavy cars weighing 44,000 to 50,000 pounds each. Of these heavy cars 459 are equipped with four 50-horsepower motors, and 221 are equipped with four 40-horsepower motors. The 35 lightweight cars average approximately 29,000 pounds, and are equipped with four 25-horsepower motors. These weights may be compared with approximately 35,000 pounds for the average PCC car. Practically all of the heavy cars are equipped with field shunting devices which, while resulting in higher consumption of electricity, have resulted also in increasing our average speed. The average speed of our railway cars for 1938 amounted to 10.72 miles per hour, which according to the American Transit Association records was, I believe, third highest in the nation.

It is true that the heavy cars in use on this property were designed and built 20 or 30 years ago. They were not, however, designed and built as most of the older cars which have been and many of which still are in use on many of the transportation systems of this nation. They appear to have had points of design which still make them more acceptable to our patrons as comfortable-riding vehicles than most of the older cars of other systems to which we refer. Moreover, they have been maintained considerably above the average of those of other systems. They are clean, strong, and comfortable—somewhat noisy we grant—but on the whole the continued operation of these very cars we believe has been one of the factors which has kept our company on a basis of earnings which has made it possible to keep us paying our bond interest and out of receivership. We have every respect for the operation of the PCC car, and although we have had no experience here with it or with the operation of trolley busses, we can see the advantage of their use in certain fields. We are slow to be convinced that either of these types of vehicles can now be economically substituted for the operation of our present equipment. To do so would result in the destruction of a remaining value in our present equipment which we feel would not be compensated for in the new equipment. Moreover, our experience with our own lightweight cars makes us rather skeptical that the PCC car with its small wheels and relatively light weight can give adequate service during our winter months, bucking snowdrifts which accumulate here during these months and contending with the low temperatures which also contribute to the spinning of wheels and the slowing up of service. We have found our own lightweight cars to be inadequate in snowstorms and low temperatures, and conversely we have found that our heavy cars powered with 40- and 50-horsepower motors do maintain our schedules during winter months even though our wheel wear during these months averages six times as great as it does during the summer months of June, July, and August. Under the circumstances, therefore, it appears to us that the substitution of these new types of rolling stock for our present standard cars must be predicated upon our being relieved of the expense of rebuilding of a substantial section of wornout track and paving in a particular route. Having such a route up for consideration, decision as to whether to substitute trolley busses or gasoline busses must rest upon the principles outlined by Professor Hoard in this paper.

While we may not agree that the time is ripe here for the substitution of some of the newer types of equipment, this very fact can be brought out most effectively by such an analysis as Professor Hoard has presented in this paper.

H. A. Perryman (nonmember; Los Angeles Railway Corporation, Los Angeles, Calif.): This paper has been developed with considerable labor and research and is based necessarily on assumed averages for various operating and traffic factors. As an academic study the paper shows considerable enterprise and has, in my opinion, a decided value in the field of research.

In general, these assumed averages do not apply to this property, with the result that the charts as developed cannot be applied to specific lines operated by the Los Angeles Railway.

The study is based on an average 6-cent fare which is higher than our average fare (4.51 cents) and an average speed of 13 miles per hour which is higher than our average rail speed (10.5). Rates of depreciation and interest are also different.

The study is also based on two assumed averages, which are not often found on our lines, namely *L*, or the average loading of vehicle, and *m*, or the ratio of the cars per hour in the peak to the average base cars. Table I of this discussion is a tabulation showing the values of *L* and *m* on our rail and principal coach lines.

The study is based on interest rates for new money only, and does not make any allowance for interest on tracks already in place and in good operating condition. As a result of this the values of *A* in the charts (PCC cars with no track rehabilitation) are somewhat delusive.

The study is based, of course, purely on engineering and/or accounting data and does not take into consideration the operating policy of the company or the popular requirements of the districts to be served.

In planning the modernization of a line or property, the nonengineering considerations, particularly public sentiment with regard to the choice of street car, trolley bus, or bus, are of primary importance.

George L. Hoard: There are in this country transit systems of almost all degrees of preservation. On some systems the equipment is old and run down, with very little useful life remaining. Contrariwise, on others the standards of maintenance are much above the average. Equipment that nominally belongs to a previous generation has been rebuilt one or more times, so that while its appearance may not compare favorably with the latest in modern vehicles, its operating characteristics and cost of maintenance may be reasonably satisfactory. The discussion by Mr. McWethy indicates very strongly that the property of the Twin City Rapid Transit Company falls in the latter class.

Table I. Los Angeles Railway Corporation—Passengers Carried, Load Factors, and Equipment Requirements

	Miles of Route (One Way)	Passengers Carried in 1938 (Thousands)	Passengers Per Mile of Route (Thousands)	Passengers Carried Daily	Number of Trips Daily	Number of Seats	Value of L	Value of m

64 Highland Park	5.97	1,414	254	4,600	195	30	0.8	1.2

L—Average loading of vehicle, that is, the ratio of the average number of passengers per trip to the vehicle seating capacity, in decimals.

m—Ratio (in decimal) of the cars per hour on the peak to the average or base cars per hour.

This diversity in the condition of present equipment and its associated variables makes it practically impossible to offer a general solution to the question of when will it be more economical to modernize a system or to keep the present equipment in service. Each specific case must of necessity be an individual problem. For this reason, attention is confined in the paper to the case where the present equipment has little useful life remaining.

However, the methods of analysis outlined in the paper are equally applicable where the present equipment may be in good repair. The decision here usually rests on more precarious ground, however, for the reason that if the new equipment is to show a better return than the old it must produce an increase in riding. This increase in riding must be estimated, which is a matter of personal judgment and hence somewhat uncertain at best.

The paper clearly indicates the value of an increase in patronage to a transit system. It also suggests the importance of fast, frequent service with attractive vehicles in encouraging riding. Mr. Josephs, in his discussion, points out the importance of merchandising transportation. Undoubtedly much more attention will be paid to merchandising of transportation in the immediate future. In this respect, the advantages are with modernization. It is much easier to sell transportation with modern streamlined vehicles than with their predecessors. As pointed out in the paper, in many instances where modernization has taken place the results have been so successful that it would have been possible to "write off" considerable in the value of the present equipment and still show a satisfactory financial return.

The figures from the Los Angeles Railway submitted by Mr. Perryman are both interesting and instructive. In general, the value of *m* will depend to a considerable degree upon community characteristics; for example, a city that is highly industrialized would normally have high peak loads. However, the values quoted are, with a few exceptions, about as one would expect; namely, one or slightly over, for the very light lines, around two or better for the lines of intermediate traffic, while on the heavy lines the value of *m* is again lower, approaching an approximate average of 1.7.

The value of *L*, as would be expected, varies over a considerable range being generally low on the light short lines and much higher on the long heavy ones where there would naturally be much local riding.

The figures quoted are particularly interesting in that they illustrate the wide variation in conditions that may obtain on the different routes of a single system, especially if it be a large one. They also indicate the possible danger, as suggested by Mr. Woods, of drawing too general conclusions from specific examples. They further point the necessity for individual study of each line if a complete picture is to be obtained.

Power Supply for Resistance-Welding Machines

Foreword

OWING to the tremendous increase in the use of the resistance-welding process during the past several years, and the magnitude of many of the more recent installations, the problem of power supply for these operations has become one of primary importance to all concerned. Resistance-welding machines present an electrical load of intermittent character, high magnitude, and extremely poor load factor, and because of these poor inherent characteristics, the providing of adequate electric service, both from the standpoint of plant electrical distribution and the power system supply, involves special considerations and methods.

The AIEE subcommittee on power supply for welding operations with members representing manufacturers, users, power companies, and the American Welding Society, has been actively studying the various phases of the problem with the fundamental aim in view of bringing about a closer relationship and better spirit of co-operation between these groups in order that each will better understand the problem from the other's viewpoint.

From the viewpoint of the power companies and users, it has been difficult in the past to obtain adequate and reliable engineering data on proposed welder installations prior to their actual installation and operation and, in addition, some of the machines had exceedingly poor electrical characteristics. From the viewpoint of the manufacturers and users, there have been instances where they have been unable to get proper service connections from the power company for handling welder loads. Such refusals to provide service were, no doubt, justified in some cases but others may have been due simply to a lack of interest in the load by the power company and a concern that the load might be disturbing to other customers. Sometimes the user has not adequately prepared for the welder load by the installation of proper bus and transformer facilities with the result that welds are poor and results inconsistent. It is certain that many of these cases of poor co-operation and unsatisfactory installations have been due to a lack of knowledge of all the pertinent facts.

The subcommittee has been working for some time on a series of three reports covering the various phases of the general problem of electric service for resistance welders; two of these are presented herewith:

I. Guide to good electrical performance of resistance-welding machines

II. Resistance-welder installations

Under preparation is:

III. Factory wiring for large resistance welders

It is the hope of the subcommittee that these reports will assist, at least in some small measure, power engineers, industrial plant engineers, welding machine engineers, and any others actively interested in resistance welding in the planning of layouts for welder installations and also in the purchase of new equipment.

I. Guide to Good Electrical Performance of Resistance-Welding Machines*

Purpose of Report

Resistance welding consists of clamping two or more pieces of metal between electrodes and passing electric current through them for the purpose of joining the pieces by fusion of the metal. The adequacy of supply and proper control of this electric current are determining factors in the production of consistently good welds. Relatively high values of current are required at the weld, and the electrical characteristics of the welding machine determine the amount of current which must be drawn from the electric supply lines when delivering these high values of welding current. An efficient machine of good electrical characteristics and low kilovolt-ampere demand requires a much smaller plant investment for transformers, feeders, etc., than the machine with poor electrical characteristics and resulting high kilovolt-ampere demand, although both may deliver the same welding-current output.

This report shows what is meant by good electrical performance and outlines factors upon which good electrical characteristics are dependent. A better understanding of what constitutes such good characteristics will bring about a better appreciation of them by the users of the equipment. Concurrently, as the art advances and the demand for improved designs increases, the manufacturers will meet these demands with continued improvements in their machines. There are several recent developments that eventually may result in radical reductions in demands of resistance welders and a resultant easing of the power-supply problem, but until such machines are commercially and economically available, a thorough understanding of the electrical characteristics of the present-day conventional machines is necessary if they are to be economically served.

It is intended that the report shall assist the purchaser in the preparation of specifications for the purchase of welding machines of the best electrical design, thereby minimizing the problem of power supply. Among the more common types of machines to which it applies are spot, projection, butt, flash, seam, and portable welders.

The report has been made very general in nature and to all who are closely associated with the electrical industry, it may appear that too many elementary factors are discussed, but to production and industrial engineers who represent perhaps the largest single group interested in welding as a production tool, the report should fill a long-felt need in acquainting them with the electrical problems associated with resistance welding.

Scope of Report

The report covers the following subjects:

1. Electrical characteristics of welding machine:
   - (*a*). Kilovolt-ampere demand
   - (*b*). Kilowatt demand
   - (*c*). Power factor
   - (*d*). Heating
   - (*e*). Welder primary voltage
2. Power supply and its effect upon welder performance
3. Secondary circuit of welding machine
4. Welder transformer
5. Control equipment
6. Name-plate data for welding machine

Papers 40-57 and 40-58, prepared by the subcommittee on power supply for welding operations of the AIEE committee on electric welding, recommended for publication by the AIEE committee on electric welding, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 27, 1939; made available for preprinting January 4, 1940; released for final publication February 26, 1940.

Personnel of AIEE subcommittee on power supply for welding operations: L. W. Clark, *chairman*; E. F. Dissmeyer, M. B. Gathman, C. E. Heitman, W. F. Hess, E. A. Hester, H. S. Hubbard, S. M. Humphrey, A. H. Lewis, G. S. Mikhalapov, C. L. Pfeiffer, F. H. Roby, and F. B. Sanford.

* **Paper 40-58.**

Electrical Characteristics of Welding Machines

The electric current required at the weld is supplied by means of a welding transformer which reduces the supply or plant voltage to a relatively low value (usually less than 20 volts). By this method the current from the supply lines is stepped up to the high value required for welding. The magnitude of actual welding current required depends upon many interrelated factors, such as the type of weld, material being welded, the geometry of the pieces, applied pressure, time of current flow, and perhaps others, all of which are beyond the scope of this report.

The current drawn from the supply lines, while also dependent upon these same factors, is in addition greatly affected by the design and physical arrangement of the welding machine itself. The ratio of the welding or secondary current to the supply or primary current is the best relative measure of the desirable electrical characteristics of two machines of the same secondary current output and the same primary voltage rating. The higher this ratio, the more desirable will be that particular machine, other factors being equal.

KILOVOLT-AMPERE DEMAND

The kilovolt-ampere demand is the primary or supply current multiplied by the rated primary voltage and is also approximately equal to the secondary current multiplied by the open-circuit secondary voltage. (The kilovolt-ampere demand as used here in referring to the machine is the instantaneous demand as measured by an oscillograph and should not be confused with the integrated demand of the power meter used for billing purposes.) It bears no relation to the kilovolt-ampere rating of the welding transformer except that it will usually be somewhere between one to about six times as great.

The kilovolt-ampere demand is a direct measure of the desirable electrical characteristics of the machine design—the greater the kilovolt-amperes, the poorer the machine for equal outputs of secondary current.

The kilovolt-amperes taken by a given welder will be a maximum when the electrodes are short-circuited and when the voltage taps are set to give the maximum secondary voltage. When the machine is actually welding, the kilovolt-amperes will always be less than the short-circuit maximum because the impedance of the material being welded causes a reduction in secondary current. If the material being welded is nonmagnetic and of low resistance, such as copper or aluminum, the short-circuit condition is rather closely approximated.

KILOWATT DEMAND

The kilowatt demand of a welder reveals very little regarding the machine characteristics. (The kilowatt demand as used here in referring to the machine is the instantaneous demand as measured by an oscillograph and should not be confused with the integrated demand of the power meter used for billing purposes.) It represents the energy component of the kilovolt-ampere demand.

POWER FACTOR

The power factor is the ratio of the resistance to the impedance of the welding machine and is also equal to the kilowatt demand divided by the kilovolt-ampere demand. In general, the power factor of a welder should be as high as possible commensurate with satisfactory welding performance. Usually the more efficient and better designed machines will have higher power factors accompanying lower machine impedances and lower kilovolt-ampere demands.

However, high power factor in itself is not necessarily a guarantee of an efficient machine. With the welding electrodes short-circuited, the impedance of the machine measured at the primary terminals of the welding transformer should be as low as possible. This impedance is composed of resistance and reactance and can be reduced by reducing either or both of these quantities. If both are reduced in the same proportion, the power factor will remain unchanged. If the reactance is reduced and the resistance is kept the same, the over-all impedance will be reduced and the power factor increased. On the other hand, if the reactance is not changed and the resistance is increased, the power factor will be increased, but also the over-all impedance will be increased and the efficiency reduced which is highly undesirable. It is, therefore, insufficient to state merely that the machine power factor should be high, because the high power factor might be obtained by the latter method mentioned above. High power factor is advantageous only when accompanied by low over-all impedance and obtained by reduced reactance rather than increased resistance.

The approximate power factor of a machine must be known when calculating the voltage regulation of the electrical supply system due to the welder operation. However, an accurate knowledge of the maximum kilovolt-amperes drawn by the welder is of much more importance than an accurate knowledge of the power factor ratio and, in general, results obtained when using estimated power factors are reasonably satisfactory.

Tests of many flash, butt, spot, and projection welders show that the usual range of power factors for the larger machines (50-kilovolt-ampere rating and up) is between 20 and 40 per cent, and that for estimating purposes the use of 30 per cent power factor, coupled with the known value of kilovolt-ampere demand, will prove reasonably accurate. Similarly, 40 per cent power factor can be used for machines of 10- to 50-kva rating, and 60 per cent power factor for machines under 10 kva in size.

HEATING

The heating of the machine is another important consideration due to the fact that the insulation life of the welding transformer is a function of operating temperature. The manufacturer shall provide ample cooling of transformer and secondary loop to prevent overheating at the rated current and duty cycle of the machine. (The duty cycle is the per cent of time that current flows, averaged over a definite period. The length of the period depends upon the class of equipment and is, for example, one minute for electronic control devices.) A duty cycle of 50 per cent has been adopted as standard for rating purposes and the transformer kva rating is an indication of the allowable heating load for which the machine is designed.

WELDER PRIMARY VOLTAGE

If possible, the larger welding machines should be supplied from 440 or higher voltage sources due to the fact that the primary current demand is inversely proportional to the primary voltage, everything else being equal. The use of higher voltages assists in keeping voltage drop or regulation at a minimum.

Power-Supply Requirements and Welder Performance

Allowable voltage drop rather than allowable heating usually becomes the limiting factor in determining supply conductors and transformers because of the extremely low operating duty cycles of most welding operations. The supply to the welders should be such that the maximum voltage fluctuation or dip, measured at the last point on the welder bus or distribution wiring which is common to two or more machines, does not exceed 10 to 15 per cent. (This value of 10 to 15 per cent applies to the welding circuit and is not to be confused with the usual limitation of one to two per cent for lighting circuits affected by the welding load.) It is highly desirable to provide a system which will keep the voltage fluctuation within the ten per cent limit if consistently good welds without an excessive number of rejects are to be expected. In extreme cases the 15 per cent limit might prove satisfactory, and there are conversely some few applications in which the ten per cent limit might be excessive.

The nominal base voltage may vary gradually from time to time throughout the day due to general plant load changes and other factors, and no attempt is made here to specify an allowable range for this gradual shifting of the base voltage. Obviously, if the gradual change is appreciable from, say the day operating shift to the night operating shift, it might become necessary during such periods to change the heat or tap setting on all welding machines to compensate for the changed voltage conditions.

This report does not concern itself with the methods of providing service for welders, except to show the importance of keeping the kilovolt-ampere swings or instantaneous demands at a minimum. A succeeding report entitled "II. Resistance Welder Installations" describes the various commonly used methods of providing service for welders.

Small welder installations are usually served by a power company at either 220 or 440 volts, and the minimum charge for service may be roughly proportional to the magnitude of the maximum kva swing or instantaneous demand and, consequently, it is much to the advantage of the user to purchase a machine with as small a demand as possible.

Welder installations in the large factories, which either have their own power plants or are served by a power company at primary voltages, such as 2,300, 4,800, 6,600, or 22,000 volts, present a similar service problem with the exception that the plant engineer is directly concerned with transformer and distribution bus investment costs needed for the welders.

To show the importance of purchasing a welder of good electrical design, a typical example will be worked out. The welding engineer of a certain plant needs a projection welder with a maximum welding-current output of 100,000 amperes. He gets quotations from different manufacturers on machines incorporating the desired mechanical and control features for handling the particular type of work involved. The final selection eventually is between two competing machines, each having the same mechanical features and same method of control, but with the following differences in electrical rating:

	Machine A	Machine B
Rated kilovolt-amperes of transformer (50 per cent duty cycle)	300	500
Maximum open-circuit secondary voltage—volts	12	20
Maximum secondary current (maximum secondary voltage and minimum throat spacing)—amperes	100,000	100,000
Rated primary welder voltage—volts	440	440

Welder *B* was slightly more expensive than welder *A* but the fact that it had a larger transformer at first glance indicated it to be the best machine. However, a true analysis of the cost of serving the two welders shows that welder *A* is the logical selection. The basic consideration as far as welding ability is concerned, is the secondary current output and the ability of the welder to operate without overheating at a certain prescribed rate of production or duty cycle. Both welders had the same maximum current output and the productive output was guaranteed the same by both manufacturers. The larger transformer simply was needed to supply the excessive losses of machine *B*. The approximate kilovolt-ampere input for machine *A* is:

$$\frac{(100{,}000\times 12)}{1{,}000} = 1{,}200 \text{ kva}$$

and for machine *B* is:

$$\frac{(100{,}000\times 20)}{1{,}000} = 2{,}000 \text{ kva}$$

Assuming that a 1,200-kva step-down power transformer is needed to serve welder *A*, it would be necessary to go to a 2,000-kva transformer for machine *B* for the same voltage regulation. At $3 per kilovolt-ampere, this amounts to $2,400 added investment for machine *B* in transformer capacity alone. Conductor costs for bus and distribution are correspondingly greater for the machine with the higher kilovolt-ampere input. The plant engineer who is responsible for costs of service for the welding operations will certainly select welder *A* as the most economical and desirable machine. The welding engineer who is interested primarily in machine output and production, is equally satisfied as both machines are equal in this respect.

In addition, there is always an upper limit of allowable kilovolt-ampere demand, the exact magnitude depending either upon the factory's location with respect to the power company's substations and power lines or the size of its own generating plant.

In case of power company service, the point of connection to the power company's system determines the allowable size of welder that can be handled. The sudden flow of welder current through the system impedance causes a momentary voltage fluctuation which, if of sufficient magnitude, results in lamp flicker for all lighting customers at that and nearby locations. The farther the point of service is from the main generating plants and larger substations, the greater the system impedance and resultant voltage fluctuation for a given size welder. Voltage fluctuations must be kept within accepted limits for lighting customers. These limits vary, depending upon the frequency of the fluctuation and, in some cases, if the frequency is high, such as with certain types of seam welders, the allowable voltage fluctuation may be as low as one-half volt at the lamp, and for ordinary frequencies experienced with spot, projection, and flash welders may be as high as one and one-half to two volts.

Whenever the kilovolt-ampere demand of the welder is great enough to cause lamp flicker at other nearby customers, there are only two fundamental changes which can be made to eliminate the flicker. The system impedance beyond the point of service common to the lighting and welder loads can be reduced or the sudden flow of current through that impedance can be reduced. There are numerous methods for accomplishing either of these changes, such as reducing the system impedance by increasing substation and line capacity, tapping the welder load direct to the transmission system, separating the lighting and welder loads and serving them from separate substation bus sections, or reducing the amount of current by the use of series capacitors, synchronous condensers, phase balancers, or motor generator sets. Most of these methods involve expense of some considerable magnitude which must be passed on to the user of the welder. Obviously, if the purchaser of the welder can select a machine of more efficient design with a kilovolt-ampere demand within the allowed limit for that particular location, such expensive power-system changes or the addition of corrective equipment would not be needed. It is, consequently, much to the advantage of the prospective purchaser of the welder to obtain in advance of the purchase the allowable maximum kilovolt-ampere demand that the power company can permit at that location and then, if at all possible, select a machine that will produce the desired welding current without exceeding this allowable kilovolt-ampere input.

Welders of large size can usually be served readily in large industrial areas which generally have concentrations of power quite separate from any lighting services. The main business sections of large cities do not usually have distribution facilities suitable for welders and generally the cost of providing service at such locations is prohibitive even for relatively small machines. Suburban areas and small towns are also very likely to be unsatisfactory and expensive locations except for the smaller machines.

Secondary Circuit of Welding Machine

The single, most important factor in keeping the kilovolt-ampere demand low is the design of the secondary circuit of the welding machine regardless of whether it is a spot, seam, or other type of welder.

In order better to understand why this is so, it is only necessary to consider from the fundamental angle what is required to make a given weld. As a simple illustration, suppose a welding machine is required to spot weld two pieces of 16-gauge SAE 1010 cold-rolled steel. From existing engineering records the design engineer would possibly conclude that to obtain the desired quality weld, it would be necessary to limit the time to eight cycles and to pass 12,000 amperes through the parts to be welded.

The next point to be considered is the geometry of the parts to be welded since they, in turn, will dictate the minimum clearance in the secondary circuit of the welding machine which will permit properly placing the parts to be welded between welder electrodes. In this case, perhaps a 12-inch throat depth and 7-inch clearance between horns would readily admit the work to be welded. The next step is to determine the voltage necessary to cause the required 12,000 amperes to flow through this 12-inch by 7-inch secondary circuit with the work in position. This voltage might be found to be four volts which would immediately establish the kilovolt-ampere demand of 48 kva. If, on the other hand, a machine had been selected with a throat depth of 24 inches and a horn clearance of 12 inches because it looked as though it was plenty big enough for the work and would also permit welding a larger job at some future date, a voltage as high as ten volts might have been required to give the 12,000 amperes, thereby imposing a demand of 120 kva on the distribution system and penalizing everyone concerned forever after.

From this it may be concluded that the first rule in obtaining a machine with a minimum demand for a given welding operation is to pick out a machine with a clearance that is just large enough for the work to be done, fully recognizing the fact that if any larger clearance exists, the demand is going to be larger than it need be. There are, of course, cases where the user definitely has need for a larger throat for a certain portion of his work and he must then either put up with a larger than necessary demand on smaller parts or perhaps purchase two machines.

Having determined the throat clearance which is to be furnished in the machine, there are other factors which influence the demand, such as the actual design of the machine having this throat depth. These matters are entirely in the hands of the welding-machine manufacturers and it may be said that they, as a group today, are doing their utmost to reduce the impedance of their welding machine circuits in order to reduce to a minimum possible voltage disturbances in plant-distribution and power-system lines.

The prospective purchaser of welding machines can be assured of the merit of the electrical design of the machine being purchased, by comparing the secondary current outputs and the kilovolt-ampere inputs of the machines being considered. For the same secondary current output the machine having the lowest kilovolt-ampere input will be the lowest impedance machine and, consequently, the most desirable from this angle. The purchaser can also observe the physical geometry of the welding machine parts and select a machine in which the transformer is placed as close to the useful throat of the machine as possible and in which the flexible connections are so arranged as not to introduce excessive reactance.

Portable Welders

In the case of portable welding machines, the same fundamental principles apply. There is here, however, another factor to be considered and that is the type of cable used between the transformer and the gun, assuming, of course, the same principles regarding clearances have been applied to the gun as were mentioned above in regard to the throat of the welding machine. Here it is important that (1) cables no longer than necessary are selected, (2) that in the case of parallel conductors, cables be strapped closely together at all times to reduce the reactance, and (3) that full consideration be given to single, low reactance, interleaved, and concentric designs of cable which are now on the market and which substantially reduce the demand during weld.

Welder Transformer

The transformer incorporated as part of the complete welding machine should be built in accordance with the latest revision of the AIEE Standards No. 39 as soon as this revision can be accomplished. In the meantime the latest Resistance Welder Manufacturers Association Standard, which is a carefully drawn one, can be relied upon. The transformer name-plate rating is based upon a 50 per cent duty cycle and indicates the kilovolt-ampere load it can safely carry at 50 per cent duty cycle. It in no way indicates either useful output of the machine in welding current, or the maximum kilovolt-ampere input to the machine from the supply lines. The equivalent continuous ratings corresponding with loads at various duty cycles are:

70.7 per cent of the load at 50 per cent duty cycle

31.6 per cent of the load at 10 per cent duty cycle

22.4 per cent of the load at 5 per cent duty cycle

Control Equipment

Proper control of a welding machine is essential if consistently good results are to be obtained. Many pages would be required to cover adequately and completely all the various phases of welding-machine control. It is the intention here to simply outline in as concise a manner as possible the fundamental concepts of control requirements, the various types of control equipment, and the field of application for each.

Fundamental Requirements

The energy required to produce a weld is directly proportional to the current squared, the resistance of the weld area between the electrode points, and the time during which the welding current is allowed to flow. To obtain consistent results, each of these three factors must be controlled as carefully as possible.

The welding current is usually regulated by changing the position of a tap switch on the primary side of the welding transformer or by delaying the ignition of electronic interrupters, thereby reducing the effective voltage applied to the transformer primary. In any case the transformer secondary voltage is raised or lowered to bring about the required change in current.

Contact resistance varies inversely with the pressure applied to the work. On manually-operated or motor-driven machines a limit switch can be set to close at a point equal to satisfactory welding pressure. Operation of the limit switch would initiate the flow of current. The pressure switch, actuated by means of the back pressure built up in the operating cylinder, is usually substituted for the limit switch on air-operated machines. However, an adjustable time delay introduced between the operation of the air valve and the application of power to the work, would accomplish the desired result.

Timing of the interval during which current is allowed to flow is a more difficult problem. Many types of equipment are available for this purpose. In general, the complete installation consists of an interrupter for the power line and some means for predetermining the period during which it is closed.

TYPES OF EQUIPMENT

The interrupter may be electronic, motor-driven, air operated, or magnetically operated. To apply recently adopted standard rating curves in the selection of interrupting equipment, it is essential that these factors be known:

1. Transformer maximum primary amperes
2. Required number of welds per unit of time
3. Estimated length of each weld

Control devices are classified as two different types—synchronous and nonsynchronous. The first is generally used where a premium is placed on absolute accuracy. High initial cost and relative complexity discourage universal use.

Nonsynchronous control involves an inherent possible error amounting to at least a plus or minus one-half cycle and possibly more, depending upon the nature of the equipment. In addition, it does not guard against the danger of variable transient current surges introduced by haphazard circuit closing present in nonsynchronous control. These errors become objectionable when applied to short timing periods and when the nature of the work is such that precision control is necessary. The fabrication of extremely small parts and the welding of stainless steel or nonferrous metals are usually within this classification.

A design classification for timers would include mechanical, electromagnetic, electrostatic, or electronic types. Final selection of a specific device should be based on the accuracy required, initial cost, maintenance cost, accessibility, range of adjustment, reliability, and simplicity.

Either the "fixed" or "current responsive" principle of current timing may be used. "Fixed timing" is satisfactory for most applications and results in less complicated equipment. Some few types of work require automatic compensation for variations in work conditions and "current responsive" systems are available for these. The machine supplier or control manufacturer will be acquainted with these requirements.

When air-operated machines are equipped with solenoid-operated valves, a fully automatic timing device performing the following functions can be used:

1. Automatic application of pressure to the work
(Squeeze Period)
2. Initiation of power flow at time interval later
(Weld Period)
3. Termination of power flow at the conclusion of the weld
(Hold Period)
4. Removal of pressure after the weld has cooled
(Off Period)
5. Reapplication of pressure after the work has been removed and new parts placed between electrodes

A low-voltage (110 volts or lower) push-button circuit is recommended to minimize danger of electrical shock.

If the voltage regulation in the welder supply lines is excessive, a separate supply line for the timer control circuit should be installed. A 110-volt lighting supply circuit is usually available for this purpose. The installation of a fusible control circuit disconnect switch separate from the power switch is considered an operational advantage although separate power and control sources are not always required.

Name-Plate Data for Complete Welding Machine

Power and industrial engineers have been handicapped in the past when called upon to plan and provide service for proposed welder installations because of a dearth of reliable and accurate information regarding name-plate and specification data for the proposed machines, particularly information about maximum kilovolt-ampere demand or load. To improve this situation the following name-plate data should appear on the name plate of the complete welding machine:

1. Manufacturer's name and address
2. Manufacturer's type and designation number
3. Rated kilovolt-amperes of transformer (50 per cent duty cycle)
4. Maximum open-circuit secondary voltage
5. Minimum open-circuit secondary voltage
6. Maximum secondary current (with maximum secondary voltage and minimum throat spacing)
7. Rated primary voltage and frequency
8. Manufacturer's serial number

From the above essential name-plate data, the following additional information can be readily calculated:

(*a*). Transformer turn ratio [rated primary voltage (7) divided by maximum open-circuit secondary voltage (4)]

(*b*). Maximum kilovolt-ampere input at rated voltage (neglecting exciting current) [Maximum secondary current (6) multiplied by maximum open-circuit secondary voltage (4)]

(*c*). Maximum primary-current demand (neglecting exciting current) [Maximum secondary current (6) divided by transformer turn ratio (*a*)]

II. Resistance-Welder Installations*

Purpose of Report

Factory wiring and electrical distribution for resistance-welding loads must be designed on an entirely different basis than that for the ordinary power and lighting loads encountered in industrial plants. To provide a sound basis upon which recommended methods of wiring, types of bus construction, and transformer arrangements can be established the AIEE subcommittee on power

---

The AIEE subcommittee on power supply for welding operations wishes to acknowledge with thanks the assistance given by the following organizations in the preparation of this report: Midland Steel Products Company, Packard Motor Car Company, The Firestone Rubber and Metal Products Company, The Heintz Manufacturing Company, General Electric Company, and Crosley Corporation.

* Paper 40-57.

supply for welding operations has obtained descriptive reports of a number of commercial resistance-welder installations, in plants throughout the country. These reports show the different methods successfully employed in existing installations, and give a clear picture of some of the problems involved. It is hoped that they will serve other users of resistance-welding equipment as a basis upon which new installations can be made.

Design Principles

In reviewing these reports, it should be remembered that the majority of resistance-welding machines have instantaneous kilovolt-ampere demands several times their normal rating, and that in order to prevent excessive voltage drop at this equipment, as well as at any nearby equipment, the supply and distribution facilities must be designed on the basis of the peak kilovolt-ampere demand rather than the normal rating of the machine. From a standpoint of voltage regulation the supply and distribution system must be such as would normally be employed if this peak kilovolt-ampere demand were drawn continuously. However, due to the low operating duty cycle of this load, its heating effect on the system is usually extremely small.

Since the capacity of all power equipment and distribution systems is based on heating or temperature-rise limitations it is seen, therefore, that in order to serve one resistance-welding machine, the normal capacity of the system must be much higher than necessary from a heating standpoint in order to satisfy the conditions of voltage regulation. In fact, in designing a system to supply two or three or even ten welding machines operating on the usual duty cycle encountered, it is safe to neglect the consideration of heating capacity required and design the system to satisfy the consideration of voltage drop. It is only when a considerable number of machines are involved on a single system that the heating becomes a consideration of any importance, or when the duty cycle of a single welder exceeds about 25 per cent, such as with most seam welders.

Summary

In the following representative welder installations, several types of feeder distribution systems are represented. Two of the companies employ a bus system to which the individual welders can be readily and quickly connected or disconnected. Tap points are available at regular intervals and the welding machines can be moved around from season to season with very little expense. The same is true, to a lesser degree, of the wire or cable feeders used by the other companies. This type of feeder does not lend itself quite so readily to frequent changes in plant layout, but is generally cheaper and easier to install.

The bus system employing the concentric arrangement of copper tubes will be found to have the lowest voltage drop, and where this factor is of major consideration this type of feeder is of highest efficiency. In installations where the equivalent thermal loading is high, this type of construction may be unsatisfactory since the heat radiation or conduction from the inside conductor is comparatively low. However, should it become necessary, cooling air can be forced through the inner conductor thus raising its load capacity. The system of interlaced copper bus bars, usually has a high load capacity, but gives a slightly higher voltage drop than the concentric construction.

The system of cable construction is of course the simplest, since the problems of insulation are minimized. In general this type of construction gives a higher voltage drop and lower load capacity than either of the above types. However, if the various conductors are interlaced and spaced very close together the voltage drop can be reduced to a value comparable with the bus-type construction. In so doing the load capacity is reduced due to the reduced radiating surface, and this must be compensated for by a sufficient number of parallel lines to reduce the thermal loading to the safe point.

Table I shows the ratio of total connected welder load to total supply-transformer capacity for the various installations, the ratio of largest single welder to total supply-transformer capacity, and the ratio of resultant thermal load to total connected load. The first ratio in some cases may be determined by the thermal loading of the system and thus be dependent upon the average operating duty cycle of the units comprising the installations. If the average operating duty cycle is high, the thermal loading will be high and this ratio must be low. The ratio of largest single unit to supply-transformer capacity is usually determined by the requirements of over-all voltage drop. If a large part of the permissible voltage drop is consumed in the feeder line, the allowable drop in the supply transformer is small, and this ratio must be small. In most commercial installations it is this consideration of voltage drop that determines the supply-transformer capacity, rather than the consideration of thermal loading.

It will be noted that the ratio of total connected load to total supply-transformer capacity varies from 0.4 to 8.74, but the weighted average is about 2.0. This wide variation may be partly explained by the fact that the method of rating resistance-welding equipment has, in the past, been rather vague, and the values of connected load taken from the name-plate ratings may be

Table I. Summary

Company	Feeder	Phases	Power-Transformer Capacity	Connected Load	Type of Service	Ratio Total Connected Load to Total Supply-Transformer Capacity	Ratio Largest Single Welder to Total Supply-Transformer Capacity	Ratio of Thermal Load to Total Connected Load

F		Three	1,500	2,400	Miscellaneous	1.6	0.267	0.177

quite at variance with the now commonly accepted practice of rating equipment on the basis of a 50 per cent duty cycle. For example under company *C*, section 6, we see that a normal current of 300 amperes applies to four different sizes of equipment, namely 50, 75, 100, and 150 kva.

Figure 1. Schematic diagram of welder supply system—company A

The minimum value of 0.4 applies to a projection welder operating from a special supply transformer, and supplied by means of a concentric-cable feeder. Obviously the major consideration in this case is that of voltage drop.

The maximum value of 8.74 applies to an installation having a relatively large number of units. In such an installation the probability of a large number of units operating simultaneously is rather remote, so that from a standpoint of voltage drop, the required capacity of the supply-transformer bank is determined by the size of the largest single unit. In this instance the ratio of largest single unit to supply-transformer capacity is 0.4.

Another factor which makes for low supply-transformer capacity, in this case, is the use of the low-impedance concentric tubular bus. This type of bus gives a comparatively low voltage drop, so that a higher impedance (lower capacity) supply-transformer bank can be tolerated. The chief reason for the ability of company *C* to serve 13,119 kva of welding load with only 1,500 kva of supply-transformer capacity, is their use of a good concentric bus design with extremely low impedance. This permits serving an exceptionally large factory area by the single-bus system without obtaining excessive voltage drop at the welding equipment. Other types of bus construction and cable assemblies cannot serve as large an area, nor as many units, without excessive voltage drop. The result is that where such construction is used there must be more feeders operating in parallel or a higher supply-transformer capacity.

Where a large number of smaller units are to be served, the thermal loading of the supply transformers and feeder lines may become the determining factor. This determination, however, depends upon a knowledge of the operating duty cycles of the various equipments. In this particular case the average operating duty cycle is comparatively low, the ratio of average kilovolt-ampere load to connected kilovolt-ampere load being 4.8 per cent. The ratio of average kilovolt-ampere load to supply-transformer capacity is approximately 0.4, the extra capacity being necessary to limit the voltage regulation.

The ratio of largest single unit to supply-transformer capacity varies from 0.3 to 1.5, with a weighted average of about 0.5. The maximum value of 1.5 applies to a seam-welder installation in which the thermal loading of the system is the determining factor in selecting supply-transformer capacity.

The ratio of thermal load to total connected welder load for these commercial installations of all types except seam welders is between 0.048 and 0.177, and for seam welders, between 0.44 and 0.67.

It must be remembered that it is impossible to give any definite empirical values for any of these ratios, since the proper values depend upon individual conditions. The values given in table I do, however, give a general idea as to the practice followed in some of the industry's successfully operating installations.

It is interesting to note that in all of these installations overload protection of the feeders and transformers is confined to instantaneous overcurrent devices, designed to protect against short circuits. In one installation this instantaneous tripping is reduced well below the short-circuit current to provide a measure of protection against high overloads on individual welders. The protection thus afforded against individual machine overloads is very small. In so far as we are informed, the only practical overload protection is that afforded in the connections to each individual machine. This may take the form of instantaneous overcurrent trips, overtime trips, or a combination of these two, or some thermal relay or fuse with thermal characteristics similar to the equipment to be protected.

For the protection of supply transformers, the instantaneous overcurrent devices set for short-circuit currents have proved satisfactory. In installations where the thermal loading is high, contact-making thermometers immersed in the cooling oil have been employed to trip the circuit breakers when the oil temperature becomes excessive.

Another point of interest is that the power supply for the resistance-welding loads is usually separated from the general plant power supply. Generally speaking the voltage disturbances produced by the resistance-welding load cannot be tolerated on other plant loads, particularly lighting. For this reason an attempt is made to minimize these disturbances by separating the two loads as much as possible.

Installations—Company A

1. METHOD OF SERVICE BY THE POWER COMPANY

The power company provides service for all plant load, including the resistance welders, through a step-down substation consisting of two 6,000-kva three-phase transformers connected 24,000/-2,400 volts, located on the plant property as near as practicable to the load. Each transformer is radially fed by means of an underground cable from a 24,000-volt substation located about one-quarter mile from the plant. The transformer secondaries are solidly connected to the 2,400-volt bus. The 2,400-volt plant feeders are connected to the bus through oil circuit breakers and double-throw disconnecting switches, as shown in figure 1.

2. COST TO THE POWER COMPANY TO SERVE WELDER LOAD

No special consideration or expense was required by the power company to serve the welder load. The step-down substation was needed to supply the load at the voltage required, and the 24,000-volt supply to the substation was of ample capacity to take the kilovolt-ampere swings of the welder without producing troublesome flickers.

No other customers are fed from this step-down substation and so the power company has not been concerned by the flicker on the 2,400-volt bus. If, in the future, some new load develops in this area that could advantageously be fed from this substation, it might be necessary to set aside one substation transformer for welders and other flicker-producing load and use it also as the "throwover."

3. PLANT DISTRIBUTION FOR WELDERS

The welder power transformers which supply the welder bus are three 1,000-kva single-phase 2,400/480-volt 4.4 per cent impedance, connected delta-delta in a three-phase bank. They are fed from the primary room by three 250-foot lengths of 500,000-circular-mil three-conductor cables, operating in parallel. The transformers are located on the roof near the load center of the welders. The 480-volt transformer bus is made up of two one-quarter- by four-inch copper bars per phase. Solidly connected to the transformer bus are 12 three-phase feeders of three single-conductor 500,000-circular-mil cables distributed over the entire bus. These feeders are brought down from the transformer bus on the roof to the welder room in four groups of three three-phase feeders. Each group is supported in wooden cleats and taped together. In the welder room, the four groups of three feeders divide into two groups of six feeders each. One group extends about 80 feet east and the other about 160 feet west from the transformer bus. The three conductors of each three-phase feeder are taped together and supported from messenger cable strung from the building girders above the line of welders. Each welder is connected to the same phase of each of the six three-phase feeders so as to divide the load about equally among the six feeders. The different welders are connected to the three phases so as to have about an equal load division on the three phases.

4. COST DATA ON THE WELDER FEEDER

Low cost was obtained by the use of the same size copper (500,000 circular mil) throughout.

5. WELDER FEEDER PROTECTION

All connections are solid from the oil circuit breakers in the primary room to the welder. The oil circuit breaker is automatic and set for time-delay trip on overload.

6. TYPE AND RATING OF WELDERS

The welders are all flash welders of which four are rated 750 kva and three are rated 500 kva.

7. VOLTAGE DROP

Voltage-drop data given below are calculated values in per cent based on a single-phase load of 800 kva of welding current at 0.4 power factor, 480 volts.

1. At 24,000-volt bus in power company substation....................0.7
2. At 2,400-volt bus in plant switch house..............................2.3
3. At 480-volt transformer bus........4.7
4. At welder, including 65-foot welder bus...................................5.0

The voltage drop for the above four items is accumulative and represents the total drop to each point. To find the drop in any particular part of the system, for example, the drop from the 480-volt transformer bus (item 3) to the welder over 65 feet of bus (item 4) is 5.0 per cent minus 4.7 per cent equals 0.3 per cent.

8. EQUIVALENT THERMAL LOADING

The heating load on the welder feeder obtained by maximum-demand heater-type ammeters was approximately 128 amperes per phase at 2,400 volts, which was 530 kva. The heating load in per cent of total connected welder kilovolt-amperes is 530/4,500 equals 11.8 per cent. At the time these readings were taken, it was known that only 3,500 kva of welders were actually operating. The heating load in per cent of operating-welder kilovolt-amperes was 530/3,500 equals 15.2 per cent.

Company B Installation

1. METHOD OF SERVICE BY THE POWER COMPANY

This plant is fed by two 4,800-volt power lines out of a 24,000/4,800-volt step-down substation as shown in figure 2. The step-down substation consists of six 7,000/9,000-kva 24,000/4,800-volt three-phase radially fed transformers, serving six 4,800-volt circuit busses. Each transformer is linked to the rest of the substation through reactors and a linkage bus. The circuit busses occupy the lower position of a double bus arrangement with a transfer bus above. The transfer bus is a continuous section energized from the linkage bus.

Figure 3. The interlaced welder bus used by company B, showing construction and method of making taps for individual welders

Bus consists of four one-quarter by four-inch copper bars on one-inch centers, insulated by means of five one-eighth by six-inch Micarta strips

The plant primary room bus is also a double-bus arrangement with a power line feeding each bus. The welder feeders are operated on the "throwover" bus and general plant load on the other bus.

2. COST TO THE POWER COMPANY TO SERVE WELDER LOAD

Originally the power line supplying the welder load was connected to a circuit bus at the substation with only power load. On such a bus the flicker limit is three volts (at lamp voltage) which would permit 1,500-kva load swings. The plant later increased the size and number of welders until load swings exceeded 2,000 kva and caused voltage flickers of four to five volts, and complaints from other customers on this bus.

There were sufficient spare positions at the substation so that it was possible by rearranging and transferring lines to set aside one circuit bus for this welder load. At present this circuit bus carries only the load of this one power line, but the transformer is still connected to the other busses through the linkage. If the load in this substation area increases and the spare positions on this bus are needed for new load, it may be that enough of this new load will be flicker load to provide satisfactory loading for the transformer. This has happened at other substations where a bus has been set aside for special load. Another alternative might be to use the spare positions on this bus as "throwover" lines to other customers. It is not felt in this case that the power company has been put to any appreciable added expense to serve this welder load.

3. PLANT DISTRIBUTION FOR WELDERS

The welding transformers are located at three different parts of the plant and are supplied by three 4,800-volt feeders from the primary room. Feeders *A* and *B* (figure 2) serve general plant load as well as welders, while feeder *C* serves welder load only. The welders are tapped to single-phase 480-volt busses made up of four one-quarter by four-inch copper bars with the going and return bars interlaced on one-inch centers with a Micarta spacer between each bar and on each side of the entire assembly as shown in figure 3. The bus is of open construction supported from the building pillars shown in figure 4. To reduce the chance of short circuits from foreign material falling across the bars, the Micarta spacers extend about one inch above the bars. Data on each of the feeders are given below:

Feeder A

1. 350 feet of three-conductor 4/0 cable from primary house to transformer

2. Supply transformer—one 1,000 kva, single phase, 4,800/480 volt, 4.6 per cent impedance

3. Feeder bus—80 feet four one-quarter by four-inch copper bars interlaced

Feeder B

1. 654 feet of three-conductor 4/0 cable from primary house to transformers

2. Supply transformers—two 1,000 kva, single phase, 4,800/480 volts, 4.6 per cent impedance, two in parallel

3. Feeder bus—240 feet four one-quarter by four-inch copper bars interlaced

Feeder C

1. 468 feet of three-conductor 4/0 cable from primary house to transformers

2. Supply transformers—six 1,000 kva, single phase, 4,800/480 volt, 4.6 per cent impedance (two transformers in parallel on each phase)

3. Feeder bus:

Top bus—472 feet of four one-quarter by four-inch copper bars interlaced plus 85 feet of four interlaced groups of three 4/0 cables, each on about four-inch centers to another bay and there 185 feet of four one-quarter by four-inch copper bars interlaced

Center bus—512 feet of four one-quarter by four-inch copper bars interlaced

Bottom bus—140 feet of four one-quarter by four-inch copper bars interlaced

4. COST DATA ON WELDER FEEDER

The welder bus cost was $10.50 per foot installed.

5. WELDER FEEDER PROTECTION

There is no protection provided on feeders *A* and *B*. The oil circuit breakers in the primary room are nonautomatic. The oil circuit breaker of feeder *C* is automatic and set for instantaneous tripping on overload. The power company's incoming line is also provided with an automatic instantaneous-tripping oil circuit breaker, so it is doubtful if a worthwhile degree of selectivity is obtained between the plant feeder *C* breaker and the power company's breaker.

6. TYPE AND RATING OF WELDERS

The type, number, and rating of the welders on each bus are given below:

Feeder A

Projection, flash, and seam	6

Total connected load (kva)	1,250
Largest single unit (kva)	600

Test data have been obtained on two of the largest welders used.

1. 600-kva projection welder; maximum swings, 960 kva, 2,110 amperes, 450 volts at 0.347 power factor at welder (1,000 kva at substation)

2. 750-kva welder; maximum swings, 1,760 kva, 4,300 amperes, 418 volts at 0.299 power factor at welder (2,100 kva at substation)

7. Voltage Drop Caused by Welder Load

The voltage drop in per cent at various points has been calculated and is based on a load of 2,100 kva at 480 volts, 0.4 power factor.

1. At substation, 4,800-volt bus	3.5
2. At plant primary-room 4,800-volt bus	6.4
3. At welding-transformer primary	7.1
4. At welding-transformer secondary (two 1,000 kva in parallel)	11.8
5. At welder over 100 feet of four one-quarter by four-inch bus	13.0

The voltage drop for the above five items is accumulative and represents the total drop to each point. To find the drop in any particular part of the system, for example, the drop from the welder transformer secondary (item 4) to the welder over 100 feet of bus (item 5) is 13.0 per cent minus 11.8 per cent equals 1.2 per cent.

8. Equivalent Thermal Loading

There are no available data on thermal loading on the individual feeders. For the total connected load of 9,660 kva, the average kilovolt-amperes or thermal load is approximately 900 kva, or slightly less than ten per cent.

Company C Installation

1. Power Company Method of Service

The step-down substation from which this plant is fed consists of six radially fed three-phase transformers of 7,000/9,000 kva, 24,000/4,800 volts, feeding six 4,800-volt circuit busses as shown in figure 5. The transformers are linked by reactors on the 4,800-volt side. The circuit busses and transfer bus form a double bus arrangement, with the transfer bus tied to the linkage bus. The short-circuit kilovolt-amperes on each 4,800-volt circuit bus is 147,000 kva.

Each power line to the plant consists of two cables of 450,000 circular mils and supplies a separate bus at the plant primary house. In addition to the power-company supply, there are two 6,000-kw turbines at the plant which operate in parallel with one power-company line.

2. Power Company Cost to Serve Welders

The substation bus supplying this plant can stand 1,500-kva swings without exceeding the flicker limit of three volts on the substation bus. This limit has never been exceeded, and so there has been no additional expense to serve the welder load.

3. The Welder Feeders

There are two welder feeders, but since their construction is nearly identical detailed description will be given for only one of the feeders.

This feeder consists of 1,525 feet of 450,000-circular-mil single-phase cable from the primary house to three 500-kva 4,800/480-volt transformers connected in parallel. The 480-volt welder bus is connected solidly to the transformer

Figure 6. The concentric tubular bus used by company C, construction and method of support

The bus is made up of bare four-inch standard copper tubing over a three-inch extra-heavy tube with a Micarta-tube separator. Taps for the individual welders are provided every six feet

Figure 7. Showing welder bus and controls used by company C

The controls are mounted on racks alongside the bus, and consist of De-ion circuit breaker, welding contactor, and timer for each welder

secondary and extends about 633 feet through the factory and serves a large number of production-type welders. The bus is copper tubing made up of a four-inch standard tube over a three-inch extra heavy tube with a Micarta tube separator. The outer tube is bare, solidly grounded, and supported by the building girders (figure 6). There is a tap provided on the bus every six feet. The De-ion breaker contactor and timer for each welder are located on a rack by the welder bus (figure 7). The lead into each welder is made of special cable with the control wiring laid in the main cable. This cable required no conduit.

4. Welder Bus Cost

The cost of the tubular bus, made up of four-inch standard tubing over three-inch extra-heavy tubing in 12-foot sections with taps every six feet is about $9 per foot. Installation cost is extra and will depend somewhat upon local conditions.

This company uses two-inch standard tubing over one and one-quarter-inch extra-heavy tubing on the branches of the second welder bus, but no figures are available on its cost.

5. Bus or Feeder Protection

Faults on the welder bus or the 4,800-volt supply are cleared by the oil circuit breaker at the primary house. The breaker is tripped after a time delay by an induction-type overcurrent relay and is selective with the main supply breaker from the power company. Each welder tap has a De-ion type air breaker which is a two-pole breaker with the poles in parallel. This gives it a rating of 190 amperes and an interrupting rating of 10,000 amperes. The breaker is set for instantaneous tripping at about eight to ten times the breaker rating. The thermal trips were found to be unsatisfactory and have been disconnected.

6. Type and Rating of Welders Served

This feeder serves a total of 13,119 kva of welders of various types and ratings. The list given in table II is fairly representative of the types and sizes served.

7. Equivalent Thermal Loading

The following readings were obtained during normal production on the feeder which supplies welders only:

Connected kva	13,119
Normal peak kva	860
Average load kva	610
Average load kw	304
Average power factor	304/610 = 49.8 per cent
Average kva/-connected kva	610/13,119 = 4.8 per cent

8. Voltage Drop Caused by Welder Load

Voltage drops in per cent are:

1. At the substation bus, 4,800 volt . . 2.5
2. At the plant primary house, 4,800 volt 3.8
3. At the welder transformer primary, 4,800 volt 4.5
4. At the welder transformer secondary, 480 volt 8.7
5. At the welder over 633 feet of bus . . 11.3

The above figures are calculated for 1,500-kva 0.4-power-factor, 480-volt welder load supplied by one power-company line and do not take into account any assistance obtained from the plant generators.

The voltage drop for the above five items is accumulative and represents the total drop to each point. To find the drop in any particular part of the system, for example, the drop from the welder transformer secondary (item 4) to the welder over 633 feet of bus (item 5) is 11.3 per cent minus 8.7 per cent equals 2.6 per cent.

Company D Installation

There are at present 269 resistance welders installed in this plant, with the following name-plate ratings:

Number of Welders	Rating (Kva)
51	Under 5
70	5 to 25
25	30 to 50
60	60 to 100
26	125 to 175
26	200 to 300
6	350 to 400
1	500
2	600
1	750
1 five head	1,500

Electronic control is used wherever accurate timing and synchronous switching is required. In installations requiring less accurate control, ignitron contactors are now being used in place of the former standard magnetic contactor in order to cut down service costs.

Practically all the welders are at present protected by enclosed fused switches. Where control equipment and switch are located at a distance from the welder, it is customary also to include a line contactor operated from a tumbler switch at the welder. In future, however, enclosed air circuit breakers will be used with all but the smaller units. These breakers will be either manually or electrically operated, depending on their location in respect to the welders, and will have instantaneous overload trips, in some cases with an additional undervoltage trip coil operated by a thermal overload relay incorporated in the welder control.

From the standpoint of power supply, these welders may be divided into three classes, as follows:

Class I

This includes resistance welders of all types, both with and without electronic control, which are installed as separate units and obtain power from the regular 575-volt three-phase 60-cycle shop lines. With the exception of a few spot or projection welders, the name plates of which may be as high as 350 kva, these welders are not rated over 150 kva or, in the case of multiple-head machines, the individual welding heads do not exceed this limit. About 94 per cent of the resistance welders are in this class.

Table II. Type and Rating of Welders—Company C

Type	Kilovolt-Ampere Rating	Normal Current	Maximum Current	Rated Current at Rated Volts
Gun	50	150	550*	114
Gun	75	300	500	170
Hydromatics	100	300	550*	228
Hydromatics	150	300	800*	340
Spot and projection	450	5,000	6,000*	1,000
Spot and projection	50	300	650*	114

* Estimates based on test readings. This company generally figures five to eight times rated kilovolt-amperes for momentary load.

Before connecting a welder to a shop line, consideration is given to the effect of voltage drop, caused by the actual power demand during weld, on other load supplied by that line. Inasmuch as most of the lighting load is on d-c or separate a-c lighting feeders, it is possible to permit fairly large momentary voltage variations on the a-c shop feeders without undesirable results. Figure 8 shows a typical section of the 60-cycle distribution. This distribution system is designed to supply shop load, and neither its cost nor design has been directly affected by welders of this class.

The central substation *A* from which the primary feeders of this system radiate has a capacity of 30,000 kva with a calculated bus short-circuit value of 500,000 kva. Primary power is distributed at 13.8 kv three phase, grounded neutral, over 17 feeders, most of which are rated 4,800 kva and consist of three-conductor 4/0 15-kv cable. Each feeder has a five per cent current-limiting reactor which limits feeder short circuits to approximately 100,000 kva. Relaying of feeder oil circuit breakers is for short-circuit protection only. These feeders serve 24 substations each of which has an emergency tie to at least one other than its normal feeder.

Substations vary from 1,800 to 3,500 kva in transformer capacity, the more recent transformer units being 1,500 kva instead of the 600 kva shown in figure 8. Although the 800-ampere 600-volt manually operated oil circuit breaker has been standard for 575-volt feeder protection, air circuit breakers will be used in any new substation construction. This also applies to shop entrance panels.

Secondary feeders are 575 volt, three phase ungrounded, and consist usually of one three-conductor 500,000-circular-mil cable nominally rated 400 kva. If more capacity is needed a similar cable is added in parallel or a separate feeder is established. Length of feeder between substation and building may be up to 1,000 feet. Inside building feeders usually are of open construction extending the length of the building and may be anywhere from number 0000 to 1,000,000 circular mils in size. It is obvious that the larger welders in this class cannot be fed from the more remote sections of the shop 575-volt lines, and as mentioned above, each case must be considered in the light of the particular line capacity and demand involved.

Class II

This covers group installations of welders where the voltage disturbances set up by the operation of one or more of the welders, if from the shop 575-volt lines, would interfere with the operation of other welders of the same group. In some cases such installations can be supplied from the nearest substation through a special low-impedance line, but in two installations the following methods have been used.

The first group consists of 14 seam welders and one projection welder four of them having two welding transformers each (figure 8). Name-plate rating of the group is 2,524 kva, 550 volts. The 19 electronic controls required, together with their protective equipment, are mounted together on a centrally located overhead platform. Directly below the platform is installed a Pyranol-filled transformer rated 1,000 kva, 13,800/-575 volts. The low-voltage side of this transformer is connected to a short bus directly underneath the platform floor, from which connection is made through

two-pole fused enclosed switches to each separate welder and control. Each welder control is also equipped with a two-pole contactor, operated from a tumbler switch at the welder, which opens the power circuit to the welder without removing control voltage from its control panel. With all welders operating under normal production, the actual load, as measured with indicating instruments, is 1,116 kva, three phase, with a maximum unbalance between phases of $12^1/_2$ per cent, and an average 0.45 power factor. (Note that these are short-throat welders.) Bus voltage averages 549 volts with a maximum variation plus and minus of $3^1/_2$ per cent. It is probable that the average kva load over a period of several hours is slightly below the measured amount which may explain why there is no trouble with overheating the 1,000-kva power transformer.

A second installation directly adjoining the above consists of one seam welder equipped with five welding heads each with a 300-kva name-plate rating. Control consists of electronic panels mounted on an extension of the above-mentioned platform. Power is obtained from a second 1,000-kva three-phase Pyranol-transformer similar to the one mentioned above and located directly below the platform. The low-voltage side of this transformer is connected through a manually operated disconnecting switch and a 1,200-ampere three-pole inverse-time-limit electrically operated enclosed air circuit breaker directly to the five welding circuits and controls. Excitation for the controls is fed through an enclosed fused switch tapped into the line ahead of this breaker so that the breaker, which is operated from a push-button station at the welder, may be opened without breaking the control excitation. Under normal operation this welder demands approximately 1,500 kva with a 66 per cent duty cycle (two cycles on, one off) and draws, as measured with indicating instruments, 1,006 kva, three phase, with a maximum unbalance between phases of 22 per cent and an average 0.50 power factor. Supply voltage averages 525 volts with the welder in operation, and 550 volts at no load, with a plus and minus variation at either point of two per cent.

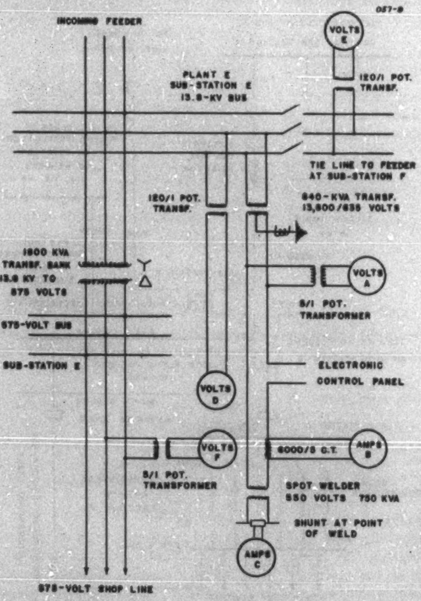

Figure 9. Location of voltage and current readings taken during test of power-supply system with 750-kva spot welder in operation —company D

The primary power supply to these two installations is taken from one of the regular shop 13.8-kv feeders *A* indicated in figure 8.

The control panel for the 13.8-kv oil circuit breaker is located on the welder control platform. Connection to the high side of each transformer is through pothead-type terminals which in turn are protected by an additional steel enclosure.

Class III

This includes large electronically controlled projection or spot welders where, although the equivalent continuous load is not great, the line-current demand at the time of making the weld is so high that it is inadvisable to supply it from the regular power transformers of one of the shop substations. In general, this applies to welders having a demand in excess of 2,000 amperes root mean square, 550 volts, during weld.

There are at present two installations that illustrate this classification. The first is a projection welder rated 550 volts, 500 kva (50 per cent duty cycle). Power for this welder is brought through a two-conductor 750,000-circular-mil concentric cable 500 feet long, from a special transformer. This transformer is rated 1,260 kva, 13,800/287.5-575-1,150 volts, and is designed to supply 15,000 amperes (peak) when connected for 575 volts. Maximum current obtainable at the welder is 2,200 amperes root mean square during weld with about 70 volts drop in the line.

The second welder in this class is a spot welder with name-plate rating of 550 volts, 750 kva, equipped with electronic control arranged for interrupted-operation welding. Power is obtained from a special transformer rated 840 kva, 13,800/635 volts and designed to give an impedance drop of less than 15 per cent when loaded at 6,000 amperes, 0.60 power factor. This transformer is located outside the building about ten feet from the welder and is fed from the 13.8-kv bus of the nearest shop substation through two lines of a three-conductor 15-kv underground cable approximately 210 feet long. This substation is in turn fed by a 13.8-kv feeder 3,800 feet in length, similar to the one shown in figure 8. Protection for both the welder and the power transformer is by an oil circuit breaker located in the shop substation and controlled from a panel adjacent to the welder. Both thermal and instantaneous overload relays are provided. Also the midpoint of the 635-volt winding of the power transformer is grounded through a current transformer which operates an instantaneous relay of low current setting to trip the circuit breaker in the event of a ground in either the welder transformer or control. The low-voltage side of the power transformer is directly connected to the control and welder through a two-pole manually operated disconnecting switch.

Recently tests were made to show the effect of the operation of this welder on various parts of the power system. The welder was operated at maximum capacity with a duty cycle of 4 cycles on and 54 off. All readings were taken simultaneously on an oscillograph with the following results. Figure 9 indicates the points at which these readings were taken.

A. Voltage of 603-volt supply to welder dropped 21.9 per cent (note that drop as read on indicating voltmeter was only 4.5 per cent).

B. Current of 603-volt supply to welder was 4,800 amperes (root mean square during weld).

C. Current in weld was 90,600 amperes (root mean square during weld).

D. Voltage of 13.8-kv bus in substation *E* at point of feed to welder power transformer dropped 9.7 per cent.

E. Voltage of the 13.8-kv tie line to substation *F* dropped 4.4 per cent. This indicates the drop on the central substation bus as this tie line is energized from a 13.8-kv feeder different from the one supplying the welder. Note that the capacity of the supply to the central substation bus was one-half normal at the time these tests were made.

F. Voltage of the 575-volt shop lines in plant *E* supplied through wye-delta-connected transformer bank substation *E* dropped 6.7 per cent.

All readings but the last were definitely taken from the same phase. It should be noted that the general plant voltage drop of 4.4 per cent (in one phase) observed at *E* is reduced one-half when the central substation bus is operating with full-capacity supply, and is probably further reduced by the time it reaches the 575-volt distribution system by the balancing effect of synchronous- and induction-motor shop load.

Company E Installation

In this plant like in many others where acquisition of new equipment and general expansion have been gradual, the majority of the welding equipment is widely scattered all over the plant. Furthermore, because of the nature of the plant's business, drastic changes in the location of a large portion of the welding equipment available are quite frequent. When they occur, certain general shifts in power loads and temporary feeds are sometimes made which result in different power-supply conditions.

For these reasons to present a general picture of the power feed of all welding equipment used would be both difficult and inconclusive. Accordingly this report is limited to a description of power supply of one group of welders which, because of the time and permanency of their installation, can be treated as an integral unit.

General Description of Equipment

The resistance-welding equipment comprising this group consists entirely of spot and seam welders. All but two are of the pedestal stationary type. One is a fully portable welding gun and one a semiportable type with provision for 30-foot travel. All stationary machines are located within 50 feet of the distribution board.

The kilovolt-ampere capacities of the equipment are shown in figure 10. It will be noted that several of the machines have full-load capacities of such magnitude that were they to form part of the normal production load unsatisfactory voltage regulation would result with the power supply available. However, the maximum production requirements of these machines are considerably lower, as shown on the "normal maximum" line, and rather than increase the power-supply installation mechanical provisions are made preventing the setting of these machines at a tap higher than the normal maximum for all work except experimental which is conducted by plant engineers only when this group is inoperative, and with one machine at a time.

Load Conditions

The total maximum load is 1,375 kva. This load, however, corresponds to operation with short-circuited secondaries. The actual working loads of these machines run 5 to 15 per cent less, depending on the machine and the material used. Assuming an average of 10 per cent, the actual maximum load becomes 1,237.5 kva. Application of this load to the 460-volt bus results in a net drop of 13.6 per cent on this bus which would be excessive from the welding point of view. In addition it produces a 5 per cent drop on the 2,300-volt bus which is also considered undesirable.

However, the application of maximum load presupposes two facts: (1) that every machine is operated at its maximum setting; (2) that every machine should fire at the same time. As the machines are operated most of the time at setups averaging 50 per cent capacity, and as the combined duty and welding cycle (time of flow of current to total operating time) is between 5 per cent and 25 per cent, the probable maximum load is considerably smaller.

Prolonged and extensive oscillographic studies of the group failed to reveal load peaks higher than 500 kva with a highest daily average around 250 kva.

No attempt has been made to measure the kilowatt or kilowatt-hour loads as no evidence of heating of transformers, equipment, or feeders has ever been observed.

Figure 10. Schematic diagram of welder supply system—company E

Power Supply

The power is supplied by two 333-kva 2,300/460-volt single-phase 3.56 per cent impedance oil-immersed self-cooled transformers connected in parallel. The transformers are installed on an outdoor platform adjacent to the floor housing the welding equipment. The 460-volt bus and distribution are thus not over ten feet from the transformer bank.

The transformer bank is fed from a 2,300-volt bus which, in addition to the welding load, also feeds a miscellaneous motor load averaging about 300 kva, two phase, with a normal maximum 15-minute demand of around 650 kva, two phase.

The 2,300-volt bus is fed by a 930-kva, two-phase transformer bank (belonging to the power company) consisting of four 333-kva 13,800/2,300-volt single-phase oil-immersed self-cooled transformers, star connected.

Distribution System

The 2,300/460-volt transformer bank is fed from the 2,300-volt bus by two 250,000-circular-mil stranded copper cables through an automatic oil circuit breaker equipped with instantaneous overload trip normally set at 500 amperes. The circuit breaker thus, besides providing short-circuit protection, provides against dangerously high overloads which would result in excessive voltage drop.

The secondary side of the 2,300/460-volt bank is connected by four 500,000-circular-mil stranded copper cables through an air circuit breaker to a fused distribution board. The individual machines are connected to the distribution board by feeders whose size is based on their length in such fashion that their voltage drop at the normal maximum load shall not exceed 0.25 per cent.

The 460-volt bus is provided with a recording voltmeter and an audible undervoltage alarm signal set to operate at a $7^1/_2$ per cent drop below the normal open-circuit voltage.

Conclusion

The extensive voltage-regulation studies, extending over a period of several years, appear to indicate that the normal voltage fluctuation on the 460-volt bus is plus or minus three per cent of the average operating voltage. Under exceptional operating conditions a drop of minus four per cent has been observed. At the same time the voltage fluctuation of the 2,300-volt bus during normal operating conditions has been plus or minus two per cent of the average operating voltage.

These voltage conditions appear to be entirely satisfactory both from the plant operating and welding standpoints. For this reason the company has discontinued the use of an automatic instantaneous-operation-type voltage regulator which was originally part of this installation. The use of the voltage regulator, although it proved to be entirely practical, did not appear to be justifiable in this case as it presented certain problems and the further improvement in the voltage regulation it offered did not appear to be essential.

Company F Installation

1. Method of Service by Power Company

The power company supplies all of the load at the plant through two step-down transformer banks each rated 1,500 kva. One bank supplies all the small loads from a 120/208-volt radial system and the second bank supplies all the large loads and welders in the plant at 240 volts. The transformer banks are supplied from a 13,200-volt circuit, which is fed from two large substation busses. The entire load is metered on the primary side of the transformers and the customer owns the transformers.

2. Cost to Power Company to Serve Welder Load

No special equipment or expense was required by the power company to supply the welder loads. Voltage dip was not great enough to cause objectionable light flicker.

3. Plant Distribution for Welders

The transformer bank supplying the welders consists of three 500-kva transformers connected delta-delta of 4.4 per cent reactance and 1.7 per cent resistance. The welders are in two groups at two widely separated locations.

The first group, of which the largest welder is rated 125 kva, is supplied over a three-phase line consisting of three sets of three 800,000-circular-mil copper conductors in parallel. Other welders in the group are taken from a three-phase bus about 100 feet long made up of two one-quarter by four-inch copper conductors per phase, also supplied from the 800,000-circular-mil conductors.

The second group, of which the largest welder is 400 kva, is supplied from about 50 feet of three-phase bus made up of four one-quarter by four-inch copper bars per phase, with a spacing of one-half inch between bars. The center lines of the phases are spaced about six inches apart.

Welder-Feeder Protection

The bus to the second group, which includes the largest welders, is connected directly to the secondaries of the power transformer. The circuit to the other group is supplied through a low-voltage air circuit breaker.

Type and Rating of Welders

The largest welders in both groups are spot welders. The first group includes 21 welders having a combined rating of 1,300 kva, of which the largest is 125 kva. The second group includes 5 welders having a total rating of 1,100 kva of which the largest is 400 kva.

Voltage-Drop Data

The following calculated voltage drops at various points on the distribution system apply to 0.4-power-factor loads, which oscillograph records show to be closely approximated:

	Per Cent	
	Location 1, 800-Kva Load	Location 2, 150-Kva Load
On 13.2-kv line at the plant	1.5	0.3
On 240-volt bus	5.3	1.0
On 240-volt circuit at welder	8.0	2.0

Equivalent Thermal Heating

The timing on all of the spot welders is between 15 and 20 cycles. The time between welds is about three seconds on the larger welder and one second on the smaller group. The equivalent kilovolt-amperes on a heating basis is about 150 kva for the larger group and was about 275 kva for the smaller group.

Upper-Air Weather Soundings by Radio

Synopsis: A radio system for upper-air weather soundings with small unmanned balloons is described. The balloon instrument comprises elements for measuring pressure, temperature, and humidity, and a miniature radio transmitter; the latter converts the response of the measuring instruments into characteristic signals modulating the emitted radio wave and sends this wave to a ground station where the signals are measured and recorded. Details of the system are given and a discussion is given of the accuracy of the upper-air observations obtained and of the tolerances permissible for component elements of the system.

I. Introduction

A RECENT significant advance in weather forecasting is based on the routine collection of upper-air data to heights of up to 25 kilometers by means of radio soundings. This paper describes a method of radio sounding now in widespread use and presents a discussion of the accuracy of the observations. This method has recently supplanted the use of airplanes carrying calibrated recording instruments for securing upper-air data.

The radio-sonde system employs an instrument carried aloft on a small unmanned balloon, and ground-station receiving and recording equipment. The balloon instrument, called a radio sonde, comprises elements for the measurement of barometric pressure, air temperature, and humidity; a radio transmitter and power supply; and means for impressing on the radio transmitter modulating frequencies which have predetermined relationships to the values of the factors measured. At the ground station, the frequencies of the received signals are measured and recorded automatically, producing a chart of temperature and humidity plotted against pressure.

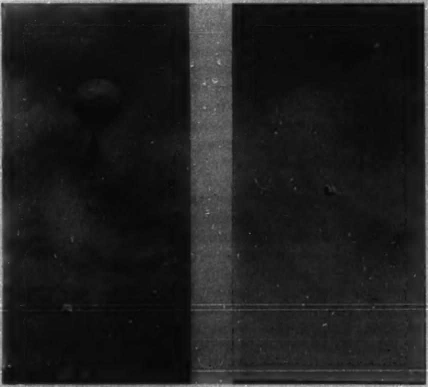

Figure 1. Radio sounding equipment during ascent and descent

Figure 1 (at the left) shows a radio sonde just as the sounding has begun. The balloon is of latex rubber and is inflated with helium or hydrogen gas to give a lift of about one kilogram in excess of the over-all weight of the sounding equipment. An ascensional rate of approximately 200 meters per minute is obtained. The diameter of the balloon is about 5 feet at surface pressure and reaches a value of the order of 15 feet before bursting; the corresponding maximum altitude ranges from 20 to 25 kilometers. A small silk parachute between the balloon and the instrument operates when the balloon bursts, bringing the instrument back to earth at a safe rate of descent. See figure 1 (at the right). The wind may carry the balloon up to 200 miles from the point of release before the equipment returns to the earth; nevertheless, more than a third of the radio sondes released are recovered and are used over again.

The potential value of our method of radio sounding was determined in experimental use by the Weather Bureau, Navy Department, and Coast Guard at 12 stations during 1938–39. The service has since been expanded to include some 30 land and 5 shipboard stations; more than 1,000 radio sondes being used monthly. This paper deals with an improved form of radio sonde using this method which incorporates a new device for measuring relative humidity; the improved instrument has been introduced at nine stations and its use at one more is contemplated in the near future.

A bibliography on radio methods for upper-air soundings was given in an earlier paper.[1] The method herein described was developed under the sponsorship of the Aerological Service of the United States Navy Department with the object of providing a new approach toward meeting the rigid operating requirements faced. In the latter stages of the development, considerable co-operation was had with Julien P. Friez & Sons, Baltimore, Md.

Paper 40-47, recommended by the AIEE committee on communication, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 8, 1939; made available for preprinting December 21, 1939; released for final publication February 16, 1940.

[1] For all numbered references, see list at end of paper.

The instrument requirements are rather severe. Measurements of pressure, temperature, and humidity are desired to heights of up to 25 kilometers. In such excursions, the range of pressures encountered may be from 1,070 millibars at the surface to 25 millibars at the top, the range of temperatures from +40 to −90 degrees centigrade, and the range of humidities from 0 to 100 per cent relative humidity. The required accuracies of measurement are ±5 millibars throughout the range of pressures, ±0.75 degree centigrade at temperatures above −50 degrees, and ±5 per cent relative humidity at temperatures above −20 degrees.

Superposed on the instrument requirements are practical requirements which increased materially the difficulty of the problem. Considerations of economy dictate that the unit cost of the radio sonde must not exceed the amount hitherto expended for an airplane sounding ($25 to $30) despite the facts that airplane soundings were generally limited to heights below 6 kilometers and that their regularity of operation was frequently interrupted by adverse weather conditions. The weight of the instrument must be kept sufficiently low (of the order of one kilogram) to allow its being carried to the desired height by a balloon of the dimensions given. However, a rugged construction is essential since the instrument must be capable of shipment by ordinary transportation to considerable distances and of storage for several months under field conditions without upsetting the original calibrations. Ease of handling by field personnel and minimum time requirements for making the sounding and for evaluating the observations are additional conditions.

From these considerations, it will be apparent that the practicability of a radiosonde design depends not only on its potential accuracy of measurement but also upon the ruggedness of the component elements required and upon the possibility of their manufacture by mass-production methods. The equipment to be described complies with the requirements outlined largely because of the special arrangement devised for carrying out the measurements and for translating them into signals which may be evaluated at the ground station.

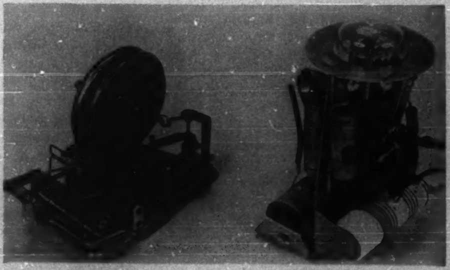
II. Technical Features of the Radio Sonde

The principles underlying the operation of the radio sonde will be understood from a study of the electrical circuit diagram shown in figure 2. As already stated, the radio sonde consists of a radio transmitter and elements for measuring pressure, temperature, and humidity. A photograph of the radio transmitter is shown at *b* in figure 3, while the pressure-measuring unit is shown at *a*. Figure 4*a* shows the temperature element and figure 4*b* the humidity element (comprising three interconnected units). The temperature and humidity elements are fastened to opposite sides of a mounting plate which fits into a ventilated compartment of the radio-sonde container. As will be shown, these elements constitute electrical resistors which vary respectively in accordance with the temperature and relative humidity of the air to which they are exposed.

1. The Radio-Sonde Transmitter

Referring to figure 2, the transmitter employs a conventional receiving-type vacuum tube having two sets of triode elements in a single glass envelope. One of the triodes is connected in a carrier oscillator circuit, operating at a frequency of 65 megacycles per second and feeding a half-wave doublet transmitting antenna. The second triode is used in an auxiliary oscillatory circuit, oscillating at about one megacycle per second and having in its grid circuit a resistance-capacitance network which operates to interrupt or "block" the oscillator at a rate inversely proportional to the time constant of this network. The capacitance is of fixed value but the resistance varies so that the "blocking" frequency ranges from 10 to 200 cycles per second. This frequency is made to modulate the carrier oscillator, resulting in an emitted carrier wave having a variable audio-frequency modulation.

The one-megacycle oscillations of the modulating oscillator (controlled by the coils L_1 and L_2 and by the capacitors C_1



(*a*) (*b*)

Figure 3. The radio-sonde transmitter and pressure-switching unit

and C_4) are used only for triggering purposes. During the oscillating condition, the grid swings positively each half-cycle and a current flows through the resistance-capacitance network formed by the capacitor C_2 in parallel with the series circuit comprising R_2, R_1, and either the temperature or the humidity resistor. (The shunt resistor R_6 sets an upper limit to the value which may be attained by the resistance in parallel with C_2.) The voltage developed across this network is applied as a negative biasing voltage on the grid. The magnitude of this biasing voltage is a function of the charging rate of the capacitor C_2 through the tube grid-filament resistance and of the amplitude of oscillation; it builds up within about 0.5 millisecond to a value sufficient to block the oscillator. During the nonoscillating condition, the capacitor C_2 discharges through the resistance combination until the negative biasing voltage is again sufficiently low to allow the tube to oscillate. This action is repeated cyclically at a rate which depends upon the time-constant of the resistance-capacitance network, which, as is evident, controls only the duration of the nonoscillating period.

In the absence of the modulating oscillator, the carrier oscillator would operate continuously. However, when the modulating oscillator begins to oscillate, its plate begins to draw current and a negative pulse is applied (through the coupling capacitor C_3) across the resistor R_5 in the grid circuit of the carrier oscillator. This voltage is of sufficient magnitude to block the carrier oscillator; the carrier-frequency oscillations do not begin again until the modulating oscillator ceases to draw plate current (because of cessation of its oscillations) so that a positive pulse is applied to R_5. It will be evident from the foregoing that the carrier wave sent out by the radio-sonde transmitter is interrupted for short periods of constant time duration, the rate of occurrence or frequency of these interruptions being controlled by the value of the resistance in the resistance-capacitance network.

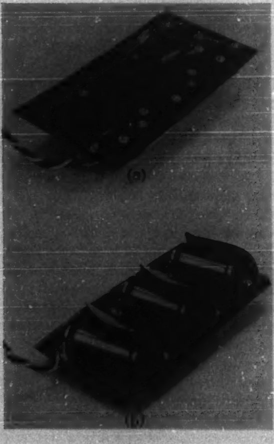


Figure 4. The temperature and humidity measuring elements

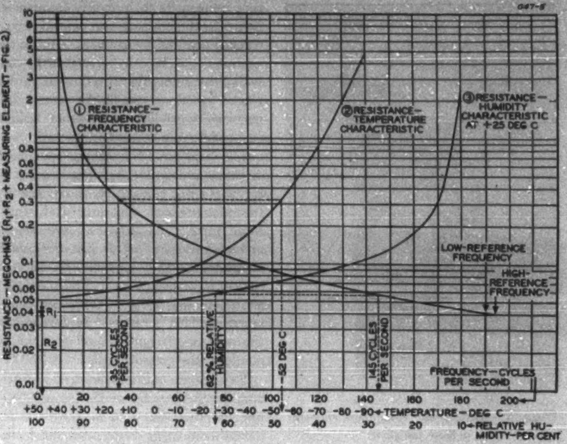

Figure 5. Curves illustrating the principles involved in the measurement of temperature and humidity

2. The Pressure-Switching Unit

This unit performs two functions, one as a measuring instrument of barometric pressure in the specified range, the other as a switch which connects into the resistance-capacitance circuit of the modulating oscillator, the temperature and humidity resistors and two fixed values of resistance known as the low and high reference. (See figures 2 and 3.) The pressure arm carries a tapered contact which bears against the polished face of a switching element at a position controlled by the ambient pressure. As the balloon rises into lower levels of pressure, the diaphragm expands laterally thereby sweeping the contactor over the face of the switching element and making the desired connections.

The switching element consists of 80 metallic strips separated by insulating strips. The conducting strips are arranged in groups of four adjacent intermediate contacts, the adjacent groups being separated by wider index contacts. The intermediate conducting strips are all connected together and to the field coil of a miniature relay which is energized upon completion of a low-voltage circuit by contact of the pressure-arm contactor with any of the intermediate conducting strips. The grounded armature of the relay normally rests against its back contact to which is connected one side of the temperature resistor. When the coil of the relay is energized, its armature bears against a front contact to which is connected one side of the humidity resistor.

By reference to figure 2, it will be evident that the relay operates to connect into the resistance-capacitance network of the modulating oscillator (in series with R_2 and R_1) either the resistance thermometer or the resistance hygrometer, depending upon whether the pressure-arm contactor bears against an insulating strip or an intermediate conducting strip of the switching element. The intermediate conducting strips are more conveniently referred to as humidity contacts since the time constant of the resistance-capacitance network and, hence, the modulating frequency of the radio-sonde transmitter is controlled by the resistance hygrometer when the pressure-arm contactor bears against any one of these contacts.

Figure 6. Radio-sonde component elements in their container

The index conducting strips of the switching element are arranged in two groups; the members of one group being connected electrically to the junction of resistors R_2 and R_1, and the members of the second group to the junction of R_1 with the two measuring elements. Contacts of the first group, comprising contact numbers 15, 30, 45, 60, and 75, are termed the high reference contacts, since only one resistor R_2 remains in circuit when the pressure-arm contactor bears against one of these contacts and, hence, a fixed high reference modulating frequency is obtained. Contacts of the second group, comprising contact numbers 5, 10, 20, 25, 35, 40, 50, 55, 65, 70, and 80, are termed the low reference contacts, R_2 and R_1 being in circuit when the contactor bears against one of these contacts and a somewhat lower fixed reference modulating frequency being then obtained.

3. THE MEASURING SYSTEM

The method employed for measuring and indicating at a remote point the values of the pressure, temperature, and humidity encountered by the radio sonde during the ascent of the balloon is now evident. The radio-sonde transmitter emits a radio wave modulated by audio frequencies which correspond successively to temperature and humidity observations. The temperature observations occur when the pressure-arm contactor passes over an insulating strip while the humidity observations are obtained when the contactor bears against a humidity contact. The changeover from temperature frequencies to humidity frequencies occurs as the pressure-arm contactor just reaches a humidity contact. When the contactor reaches successive fifth contacts, the humidity observation is replaced by one of two fixed reference frequencies depending on whether a high or low reference contact is reached.

The sequence of switching operations serves as indication, by actual count, of the particular contact being reached by the pressure-arm contactor and, thus, from prior calibration, of the actual ambient pressure. This count is much facilitated by the occurrence of the high reference frequency every 15th contact and of the low reference frequency at intervening fifth contacts. In this usage, the reference frequencies serve as index points on the pressure scale.

To evaluate the temperature and humidity observations at the ground station, it is necessary to measure the received modulating frequencies and to interpret the measurements in terms of the resistance-frequency characteristic of the radio-sonde transmitter and the resistance-temperature and resistance-humidity characteristic of the temperature and humidity elements in the radio sonde. Fortunately, for this method of measurement, it is readily possible to control the manufacture of the three elements involved (the transmitter, the temperature tube, and the electrical hygrometer) so as to attain substantially uniform characteristics. Thus, the necessity for individual calibration of the three component elements is obviated and standard charts and scales may be used in evaluating the observations at the receiving station.

The principles involved in the measurement of temperature and humidity are illustrated in figure 5. Here curve 1 is the resistance-frequency characteristic of the modulating oscillator, curve 2 is the resistance-temperature characteristic of the temperature tube, and curve 3 is the resistance-humidity characteristic of the electrical hygrometer. In later sections of this paper, it will be shown that the measurements are actually made on the basis of relative frequencies rather than on an absolute frequency basis as might be inferred from the foregoing explanation. In this way, rather large tolerances may be allowed in the manufacture of the radio-sonde transmitter without affecting the accuracy of the measurements.

4. THE TEMPERATURE ELEMENT

This device, shown in figure 4, utilizes the effect of temperature on the conduction of electricity through an electrolyte. Its construction is quite simple, as will appear from the following.

The glass capillary tube has an over-all length of 5 centimeters, a bore diameter of 0.875 millimeter, and a wall thickness of 0.4 millimeter. Capillary lengths of the required bore are purchased to a tolerance of ten per cent and, by volumetric measurements, their lengths are adjusted so as to produce an electrical resistance of 14,000 ohms (plus or minus five per cent) when filled with a standard electrolyte at +30 degrees centigrade. The capillary tubes are then bent into V form and are furnished with two glass bulbs fused to the ends. The wells provide for low-resistance contact between the electrolyte and the copper terminals of the tube, which extend through organic seals. One of the terminals consists of a very fine copper tube through which the capillary tube is filled in a vacuum chamber; the end of this copper tube is soldered to complete sealing of the device.

Figure 7. Ground-station receiving and recording equipment

The standard electrolyte used consists of a solution of 24 per cent (by volume) concentrated hydrochloric acid, 76 per cent of ethyl alcohol, and 2.7 grams of cuprous chloride for each 100 cubic centimeters of the resultant mixture. The alcohol lowers the freezing point of the electrolyte to below −100 degrees centigrade, while raising the resistivity to the desired value. The cuprous chloride operates in combination with the copper terminals to eliminate polarizing action in the tube when passing direct current.[2]

The resistance-temperature characteristic of the tube is shown by curve 2 in figure 5. Provided that excessive direct current is not passed through the tube, its calibration remains constant within 0.5 per cent for a period of a year or more.

Advantages of the device for radio-sonde application include: uniformity of calibration for all tubes filled with the standard solution, large area of exposure to the ambient temperature, rapidity of response to temperature changes, and thermal isolation from other parts of the radio sonde with consequent reduction of errors in measurement due to heat conduction to a negligible order.

5. THE ELECTRICAL HYGROMETER

This device,[3] shown in figure 4, utilizes the effect of moisture on the conductivity of a hygroscopic salt. Three units are required to give the desired variation of resistance with relative humidity. The units are mounted on the opposite side of the mounting plate from the temperature tube and rain shields are provided to prevent direct contact with rain. Each unit consists of a dual winding of number 38 American wire gauge bare palladium wire (25 turns each with a pitch of 8 double turns per centimeter) wound on a coil form one centimeter in diameter. The coil form consists of an aluminum tube having a wall thickness of 0.25 millimeter and covered with an insulating coating (0.25 millimeter thick) which is highly resistant to water. After winding, the three units are each coated with different predetermined solutions of lithium chloride in polyvinyl acetate.

The surface-leakage resistance between the two interspaced windings of each unit varies with relative humidity according to predetermined characteristics. The most sensitive coating (3 per cent lithium chloride) covers the humidity range from 10 to 35 per cent; the next sensitive coating (2 per cent lithium chloride) covers the humidity range from 25 to 50 per cent; while the least sensitive coating (1 per cent lithium chloride) covers the humidity range from 40 to 100 per cent. By connecting the three units in parallel (with suitable resistors in series with the 2 per cent and 3 per cent units), the resistance-humidity characteristic shown by curve 3 of figure 5 is obtained.

This characteristic holds only at room temperature, the range of variation of resistance being modified as the temperature decreases. This results in a progressively narrower range of humidity indication at the lower temperatures; the range at −60 degrees centigrade is from 100 to about 35 per cent relative humidity.

The electrical hygrometer has important advantages over other forms of hygrometers, particularly for radio-sonde application. In an earlier form of the radio sonde described in this paper, a variable resistor controlled by the more conventional hair hygrometer is used for measuring relative humidity. While useful observations are obtained, there are two limitations to this type. The first is that the hair hygrometer does not function efficiently at temperatures below about zero degrees centigrade; the second, that even at higher temperatures it does not respond sufficiently to the sharp changes in humidity encountered by a balloon ascending at the lowest practical rate (175 meters per minute). The electrical hygrometer overcomes both of these defects. It is characterized by a very rapid response to humidity variations at temperatures down to at least −60 degrees centigrade. Its rate of response is sufficient to permit any practical balloon ascension rate, as has been determined in actual tests at ascension rates of up to 400 meters per minute.

6. THE COMPLETE RADIO SONDE

A photograph of the complete radio-sonde assembly is shown in figure 6. A light cardboard case, covered with a metallic foil and divided into two compartments, is employed. The front compartment houses the radio transmitter *a*, the plug-in battery power supply *b*, the pressure-switching unit *c*, and the miniature relay *d*. The rear compartment supports the radiation shield *e*, for protecting the temperature and humidity elements from heating by solar radiation. The shield consists of two thin concentric aluminum tubes, the inner one of which supports the mounting plate on which the temperature and humidity elements are fastened. The shield normally extends about two centimeters above its compartment and the top edge of the mounting plate is normally flush with the top edge of the shield. The temperature and humidity elements are ventilated by the flow of air through this shield produced by the upward movement of the balloon.

The complete instrument weighs slightly less than one kilogram and its present unit price in quantities of several thousand is $27. An interesting feature of the instrument is that, with the radiation shield assembly slid down into its cardboard container, top and bottom flaps (tied back during the ascent) may be used for closing off this container. The instrument is then in convenient form for shipping or for return through the mail upon its recovery. Complete mailing instructions and the reward offered for its return are printed on the foil cover.

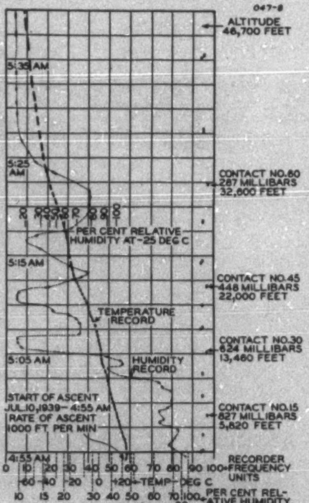

Figure 8. Record of a typical sounding

III. Ground-Station Equipment

Typical ground-station receiving and recording equipment are shown in figure 7. The receiving set *a* feeds an electronic frequency meter *b* which measures the frequency of the modulating signal from the balloon and converts it into a direct current proportional to the frequency. This is indicated by a microammeter on the electronic frequency meter and is simultaneously recorded by a recording microammeter *c*.

An important operating feature of the electronic frequency meter is that the current is directly proportional to the frequency within very narrow limits. Moreover, a control in the output circuit allows adjustment of the current corresponding to any frequency within the range by up to ±15 per cent without upsetting the linear relationship between the current and frequency throughout the range. The use made of this property is an essential feature in the use of the radio-sonde system described, as will appear later.

IV. Record of a Typical Sounding

A record of a typical sounding, redrawn for reproduction, is shown in figure 8. The start of the record, corresponding to

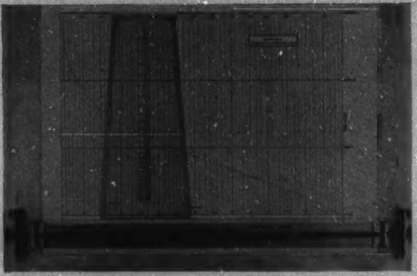

Figure 9. Illustrating the method of correlating the standard radio-sonde resistance-frequency characteristic with the standard resistance-temperature characteristic of the temperature tube

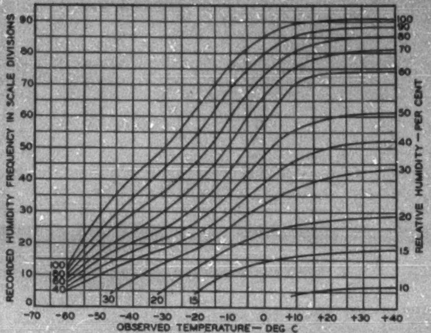

Figure 10. Charts for evaluating the relative humidity from the observed recorder frequency and the temperature at which the observation is made

the release of the balloon, is at the bottom of the chart. The recorder chart has 100 equally spaced divisions corresponding to a full-scale range of 200 cycles per second; however, it is more convenient for station personnel to work in terms of the recorder divisions which may be considered as arbitrary frequency units. For an approximate interpretation of the record, a scale of temperatures (for an average temperature bulb) and scales of humidities (at two ambient temperatures) are marked on the chart.

The traces at the extreme right of the chart represent the high reference frequencies while the traces just to the left of these represent the low reference frequencies. The physical positions of the pressure-arm contactor as these marks were being traced by the recorder may be visualized by referring to the contact numbers shown at the lower edges of the high-reference traces. (See also figures 2 and 3). The altitude of the balloon corresponding to each high-reference trace is marked on the chart as of likely interest to the reader. Altitude is determined from the air density computed on the basis of the pressure, temperature, and humidity observations.

The temperature and humidity traces are seen to form broken lines which plot, respectively, the variation of these two meteorological factors as a function of the balloon altitude. The temperature traces are readily distinguishable from the humidity traces by the nature of their variation. Each interruption of the temperature plot designates that the pressure-arm contactor has just reached a humidity or reference contact; each interruption of the humidity plot indicates that the contactor has just left a humidity contact. Light dotted lines have been added between adjacent humidity traces to emphasize the sharp variations obtained.

1. Evaluation of Pressure, Temperature, and Humidity

In determining the exact pressure level at which a given temperature or humidity trace obtains, the aerologist refers to the calibration chart for the particular pressure unit used. In this chart, heavy horizontal lines represent the reference contacts on the switching element and lighter horizontal lines represent the humidity contacts. The line thickness and spacing between lines are proportioned to correspond respectively to the widths of the conducting and insulating strips comprising the switching element. The ordinate scale thus represents contact numbers; the scale of abscissas represents barometric pressure in millibars. The calibrating points are generally taken just as the pressure-arm contactor reaches the reference contacts and a smooth line is drawn through them.

A special chart and glass scale are used for evaluating the temperature observations corresponding to particular recorder traces. The curve on the chart is the standard resistance-frequency characteristic of the radio-sonde transmitter plotted on semilogarithmic paper. The ordinate (logarithmic) scale represents resistance added in series with R_2 and R_1 in figure 2; that is, the resistance of the temperature tube. The scale of abscissas is in arbitrary frequency units corresponding to divisions on the recorder chart.

Since the temperature tube follows a fixed law of variation of resistance with temperature, the curve on the chart may also be considered to represent a plot of temperature versus generated audio frequency for a standard temperature tube and transmitter. However, in order to reduce the requirements as to the accuracy of the bore in the manufacture of the temperature tubes, the resistances of different tubes at a given temperature may differ appreciably even though they have the same temperature coefficient of resistance. This, in effect, requires that the temperature ordinate scale be permitted to slide up or down along the resistance scale. The required condition is met by mounting the chart on a drawing board and providing a glass plate bearing a vertical index line graduated in degrees centigrade which moves up or down on the chart. See figure 9.

The chart and scale together form a plot of temperature versus frequency, with means for sliding the temperature scale of ordinates to fit individual tubes. The lower edge of the glass scale rests against a movable horizontal crossbar (fastened to the drawing board) which facilitates making the adjustment.

Just prior to the release of a radio sonde, the operator measures the true temperature at the ground surface and the corresponding frequency observation from the radio sonde. These data are used in setting up the glass-plate temperature scale on the standard resistance-frequency characteristic. The operator moves the glass plate horizontally on the frequency chart so that the vertical index line coincides with the frequency corresponding to the observed recorder trace and then slides the crossbar on the drawing board upward or downward until the observed surface temperature intersects the resistance-frequency characteristic.

The chart used for evaluating the humidity observations is shown in figure 10. The ordinate scale is in arbitrary frequency units corresponding to divisions on the recorder chart. The scale of abscissas represents the temperature at which the humidity measurements are made. The graphs represent curves of equal relative humidity. Knowing the frequency of the observed humidity trace and the corresponding observed ambient temperature, the relative humidity is determined by interpolation on the chart. Reasonable control of the manufacturing processes makes it possible to obtain electrical hygrometers which conform very closely to the standard characteristics of figure 10, within plus or minus three per cent relative humidity.

V. Accuracy of the Observations

1. Analytical Considerations

It will be evident that the accuracy of the pressure observations of sounding will depend practically entirely on the accuracy of repetition of performance of the pressure diaphragm and pressure-arm linkage. Repeated calibrations of individual units show agreement of the calibration points within two millibars. A control for moving the switching element laterally with respect to the pressure-arm contactor provides for setting the unit to read correctly at the surface pressure prior to an ascent, thereby correcting for zero shift and at the same time applying a surface correction for temperature effect at ground-level pressure. The over-all temperature effect in service use is within three millibars.

The accuracy of the temperature and humidity observations depends on a number of factors which at first hand would appear to require considerable control of the component elements employed in the radio sonde and at the ground station in order to secure the required accuracy. However, simple expedients operate to reduce the tolerances to practicable values.

One expedient is to make the measurements in terms of relative rather than absolute frequency. For this purpose, the low reference frequency, having a nominal value of 190 cycles per second (95 recorder divisions), is used as a control point. From the discussion in connection with figure 2, it is apparent that the measurement of audio frequency is made merely as a convenient way of measuring the ratio of the resistance of the temperature or humidity elements to the resistance of the low reference resistor. The parameters of the vacuum tube and of the modulating oscillator circuit and the variation of these parameters even for the wide variations of plate and filament voltages and ambient temperature encountered during a sounding have but little effect upon the ratio of any two frequencies corresponding to two values of the resistance network. Similarly variations in C_2 have negligible effect upon such ratios. It is obvious then, that if the value of (R_2+R_1) is maintained within ±0.5 per cent under operating conditions and the current control in the output of the electronic frequency meter (in the ground-station equipment) is adjusted so that the recorder reads 95 divisions whenever the low reference signal is received, the observed frequencies corresponding to particular resistance values of the temperature- and humidity-measuring elements must have predetermined relationships to the low reference frequency. This is equivalent to saying that all radio-sonde transmitters may be made to have practically identical resistance-frequency characteristics whether in the laboratory or during an ascent merely by close control of (R_2+R_1). (The resistor R_4 being much higher than the other resistors, needs be controlled only within plus or minus five per cent.)

Thus, if the absolute reference frequency of a particular transmitter happens to be considerably different from the nominal value, the operator merely adjusts the frequency-meter control to make it read the standard nominal value. The same is true if the reference frequency drifts during a sounding. The small step variations in several of the low-reference traces on the record of figure 8 show where such adjustments were made.

Such small departures from the average characteristic as are found to occur in individual transmitters (after the reference-frequency adjustment is made) invariably take the form of a practically parallel shift of the curve upward or downward. The method of setting up the temperature scale on the basis of the surface-temperature data (described in a previous section) takes care of these departures in so far as the temperature measurements are concerned. A little consideration will show that, with this method, not only is the actual resistance of the temperature tube at the surface temperature taken into account, but a correction is automatically applied for the parallel departure of the actual resistance-frequency characteristic from the standard characteristic. While this correction does not apply to the humidity measurements, the requirements of accuracy of the humidity measurements do not demand such refinements.

Let us now consider what requirements must be met by the electronic frequency meter and the recorder in the ground-station equipment. The essential requirement is that the output current of the electronic frequency as indicated on the recorder trace shall be substantially linearly proportional to the received signal frequency and shall repeat this relationship within ±0.3 division under all conditions of operation. This condition must be fulfilled regardless of the actual value of the reference frequency and represents a maximum error in temperature measurement of 0.5 degree centigrade at zero degrees centigrade. Small deviations from the required linear relationship may be taken care of by applying a suitable correction factor to the standard resistance-frequency characteristic used with a given ground-station setup or, even if neglected, is largely corrected for (in temperature measurements) by the process of setting up the temperature scale just described in connection with the surface-temperature check.

On the basis of the foregoing discussion, it is apparent that temperature measurements to an accuracy of ±0.75 degree centigrade can be made with the radio-sonde system without placing undue manufacturing and calibration restrictions on either the radio sonde or the ground-station equipment.

2. Experimental Results

The curves of figure 11 provide experimental corroboration of the foregoing conclusion.[4] Curve 2 summarizes the results of 25 nearly simultaneous radio and airplane soundings. Some 100 such simultaneous ascents were made with practically the same order of agreement. The abscissas represent deviations be-

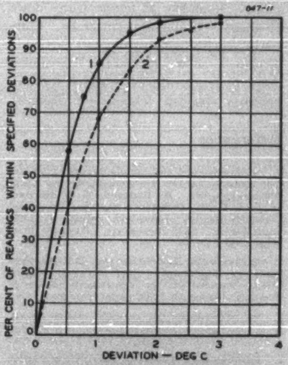

Figure 11. Summary of comparative data obtained: (1) with simultaneous radio-sonde and balloon meteorological soundings; (2) with simultaneous radio-sonde and airplane soundings

tween the two types of observations while the ordinates represent the percentages of the total observations falling within the specified deviations. In considering the results, it should be noted that the deviations include the effect of errors in the airplane instrument as well as in the radio sondes. Also, since the pressure measurements within the two types of instruments were required in computing altitude in order that the temperature observations might be compared at equivalent altitudes, the deviations include the effect of possible errors in the observations of pressure.

Curve 1 summarizes similar results for 20 soundings in which the balloon carried a recording meteorograph in addition to the radio sonde; the data from this recording instrument were obtained only after recovery. The better agreement shown by curve 1 is attributed to the fact that both instruments were tied together whereas, in the case of curve 2, the balloon was often carried away by winds up to 50 miles from the airplane at the upper levels.

In curve 1 temperature comparisons down to about −50 degrees centigrade are averaged, while in curve 2 the comparisons include data down to −30 degrees centigrade.

Similar data for the accuracy of measurement with the electrical hygrometer cannot be presented because of the lack of a standard for comparison. As nearly as can be determined on the basis of checks against a psychrometer in a controlled chamber, the electrical hygrometers agree within about three per cent relative humidity at temperatures down to about −15 degrees centigrade. Comparisons with hair hygrometers carried in airplanes show reasonable agreement down to temperatures at which the hair becomes sluggish (about −5 degrees).

Lightning Protection of Wood-Pole Lines

H. K. SELS
MEMBER AIEE

A. W. GOTHBERG
ASSOCIATE AIEE

Synopsis: The reliability of wood-pole transmission lines during the lightning season has long been a problem with operating companies. To meet the ever increasing service demands approximately 60 miles of line were reconstructed using the inherent insulation of a wood-pole line with lightning protector tubes on one of three conductors. Two years' experience with this type of construction has shown better than a 90 per cent reduction in lightning outages.

A REVIEW of the past nine years' performance on the 26-kv wood-pole lines of the Public Service Electric and Gas Company indicated that approximately 79 per cent of all interruptions were caused by lightning which represented about 38 lightning tripouts per 100 miles of line per year. This compared to a rate of 3.1 for 132-kv steel-tower lines.

After unsuccessful attempts to improve the lightning performance of wood-pole lines by the use of ground wires or wood insulation, lightning protector tubes were installed on a single-circuit 26-kv line. This line is part of a three-phase system with the neutral grounded through a 75-ohm resistor which limits the single-phase-to-ground fault currents to somewhere between 200 to 500 amperes. Since the three-phase short-circuit currents are as high as 10,000 amperes it was impossible to meet the range of currents between single-phase and three-phase faults with a single tube and a four-tube scheme would be necessary.[1] In order to reduce the cost, tubes were selected having a 60-cycle current rating of 200–1,000 amperes.

In the absence of any records at the time it was thought that the number of phase-to-phase operations would be very small. Experience showed that many of the lightning strokes involved more than one phase, resulting in the failure of a number of tubes due to the high phase-to-phase short-circuit currents. Although the number of outages was not decreased with this scheme there was very little damage to any of the transmission-line equipment and the time of outage was decreased materially.

This three-phase installation was tried for two seasons with no reduction in the number of lightning outages. In 1937 the line was rebuilt to make one phase a shielding conductor by locating it so that the remaining phases would be shielded from direct strokes. Lightning currents were drained from the shielding conductor by means of lightning protector tubes. The remaining phases were isolated from the shielding conductor and tube ground circuit by insulation sufficient to prevent phase-to-phase faults. This allowed the use of a single tube designed to withstand only phase-to-ground currents which were much less than phase-to-phase currents.

The performance of this line during the 1937 lightning season indicated that the method of protection was satisfactory but that the tubes used (15,000 to 30,000-ampere impulse current rating) would not withstand the lightning currents encountered. This conclusion was based upon the large number of tubes that failed on single-phase line outages with no phase-to-phase currents involved.

Table I. Wood-Pole Lightning-Protection Performance

	1938	1939
Miles of line (circuit)	18.9	59.4
Number of tubes installed	341	830
Tripouts	1	0
Intermediate poles flashed	0	0
Shielded phases flashed	0	0
Tube insulator flashed	1	0
Tubes destroyed	1	0
Tubes operated but failed to protect	1	0
Tubes operated correctly	103	108
Total number of tubes operated	105	108

In 1938 new tubes of a greater lightning-current rating (100,000 amperes) were installed. In addition, two more lines were rebuilt to the same type of construction, making a total of 18.9 cir-

Table III. Comparison of the Lightning Performance of Protected and Unprotected 26-Kv Wood-Pole Lines in the Same Lightning Area

	1938		1939	
	Unprotected	Protected	Unprotected	Protected
Miles of line (circuit)	48.7	18.9	53.3	59.4
Lightning tripouts	13	1	13	0
Minutes interruption	19	1	266	0
Tripouts per 100 miles	26.7	5.3	24.4	0
Minutes interruption per 100 miles	39	5.3	500	0
Reduction in outages with lightning-protection construction (per cent)		80.3		100
Reduction in minutes interruption with lightning-protection construction (per cent)		86.4		100

cuit miles. In 1939 an additional 40.5 circuit miles of line were rebuilt.

Performance

The performance of these lines during the 1938 and 1939 lightning seasons is given in tables I and II.

Table I shows the operating record, by years, of the lines rebuilt for lightning protection. The absence of intermediate-pole and shielded-phase flashovers indicates that the method of application is very satisfactory; also the very high per cent correct tube operation shows that the current rating of the tubes as now used is apparently satisfactory.

Table II is a comparison of the lightning performance of these lines before and after lightning protection was installed.

In order to eliminate the effect of variation in lightning severity in different territories and years, table III was made up to show the comparison between standard and protected wood-pole lines. By putting the lines on a common basis the operating records for the years 1938 and 1939 are compared for unprotected and protected lines in the same territory. The comparison shows a reduction of about 80 per cent for 1938 and 100 per cent for 1939 in the number of lightning outages and time of interruption.

The construction used followed the original design[2] which showed an estimated reduction in lightning outages of approximately 75 per cent. Although two years' experience indicates a greater reduction in outages it is expected that a variation in intensity and number of storms will result in less improvement than the 100 per cent obtained this year.

Table II. Comparison of Transmission-Line Performance Before and After Installation of Lightning Protection

	Before	After	
	1930–37	1938	1939
Circuit miles	63.3	18.9	59.4
Total thunderstorm line days*	3,180	150	215
Total lightning outages	204	1	0
Tripouts per 100 miles per yr	36.6	5.3	0
Tripouts per storm line day	0.64	0.0067	0
Tripouts per storm line day per 100 miles	1.02	0.035	0
Reduction in outages per 100 miles per yr by protection (per cent)		85.5	100
Reduction in outages per storm line day by protection (per cent)		98.9	100
Reduction in outages per storm line day per 100 miles by protection (per cent)		96.6	100

* An index of storm exposure which is the sum of the number of thunderstorm days as determined for each line individually.

Design

The design of lightning protection of low-voltage transmission lines incorporating high insulation strength and a shielding phase conductor with a lightning protector tube was presented in an earlier paper.[3] In brief, this system of protection is accomplished as follows:

1. One phase of each circuit is made a shielding conductor by locating it so that the remaining phases will be shielded from direct strokes.

2. Lightning currents are drained from the shielding conductor by means of a lightning protector tube.

3. The remaining phases are isolated from the shielding conductor and tube ground circuit by insulation sufficient to prevent phase-to-phase faults. This allows the use on each structure of a single tube designed to withstand only phase-to-ground currents which, in general, are much less than phase-to-phase currents.

Lightning Protector Tubes

One of the advantages of this type of protection co-ordinated with the neutral-grounding impedance is that the variation in operating conditions and future system growth and its effect upon the currents to which the protector tube may be subjected may be neglected. This is not the case when protector tubes are installed on all three phases. The lines upon which these tubes were installed are a three-phase system nominally rated 26.4 kv with the neutral grounded through a 75-ohm resistor. In one network there are two neutrals operating. In many cases if the protector tubes were to be applied to all three phases it would have been necessary to use four protector tubes where three protector tubes of a high current rating are connected in star and the star point connected to ground through a protector tube of lower current rating.[1]

In addition, where the line is long or the system is extensive, the short-circuit currents of the lines may vary widely and zoning the tubes would have been necessary had they been installed on all three phases.

Since the single-phase-to-ground fault current is limited to a value of somewhere between 200 and 500 amperes, a tube was selected having a 60-cycle current rating of 200 to 1,000 amperes and an impulse discharge current rating in the order of 100,000 amperes. These tubes were used throughout the 26-kv system for all single-phase lightning protection. In order to have the tube function properly with the system under consideration the minimum internal tube gap permitted by the manufacturer was $6^1/_4$ inches.

In order further to decrease the cost of protection a simplified tube was used. It was felt that the life of protector tubes is dependent upon weathering of the fiber and erosion of the bore during operation and that expensive hardware was not warranted. For this reason a tube was designed using standard galvanized pipe fittings for hardware and a nail electrode. Five years' experience with tubes of this type has not shown any reason for a change to more expensive hardware.

Impulse tests using standard ($1^1/_2$x40-microsecond) positive and negative waves were made on each pole top, with and without the tube electrode in place, in order to obtain volt-time breakdown curves of the pole-top assembly and tube as installed in the field. It was found that with 45-kv pin-type insulators without wood in series there was not sufficient margin between tube breakdown and insulator flashover for all points on the curves and that in some cases the curves actually crossed. This was verified by observation when the insulator flashed over without tube breakdown. Since it was necessary in rebuilding some of the lines to increase the height of the poles with a steel extension bracket, it was not practical to insulate the tube mounting and ground from the insulator pin. It was found that a shield ring installed on the tube would lower the impulse breakdown of the tube, so that within practical limits, all points on the curves were at least ten per cent below the minimum breakdown values of the shielding phase. In practice shield rings were used on all tubes where the mounting was such that there was less than six inches of wood in series with the insulator and a grounded connection.

Figures 1 and 2 are typical volt-time breakdown curves of the single- and double-circuit pole tops respectively. These are composite curves made from several sets of test data and show the margin of protection between the tube and the shielding-phase breakdowns.

Construction

An attempt was made to keep as much similarity as possible between protected and unprotected poles from both construction and appearance standpoints. It was also thought desirable to have a single-circuit pole that could be expanded to a double-circuit pole with only minor construction changes. In order to obtain the most economical construction the insulation between the shielding or struck conductor and its ground lead was coordinated with each of the shielded conductors, and to ground, for the various pole-top assemblies.

In order to conserve space in this paper photographs of the actual construction are not included. It was felt that drawings giving dimensions and other information would be far more valuable.

Figure 3 shows the assembly of a single-circuit protected pole top. It will be noted that the tube ground was brought down the pole by means of a clearance strap in order to increase the insulation between the tube ground and the unprotected phase wires which in turn increased the permissible distance between protected poles.

The unprotected pole is similar to figure 3 except that the tube, mounting bracket, and ground lead were eliminated and all grounds such as guys were attached at least two feet below the bottom crossarm.

The arrangement of the double-circuit protected pole top is shown in figure 4. Again the unprotected pole is similar except that the tubes, mounting brackets, and ground lead were eliminated with the highest guy connection two feet below the bottom arm. In addition a wooden crossarm brace was substituted for the steel brace shown on the top arm.

Location of Protector Tubes

The duty of a lightning protector tube is, in the event of short-time overvoltages, to prevent flashover between phases and flashover to ground, other than through

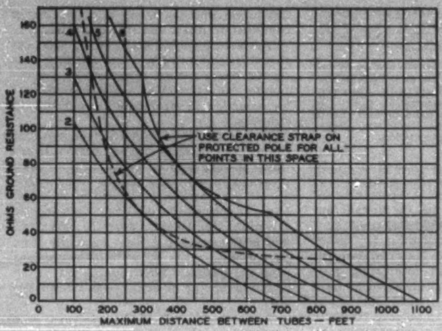

Figure 5. Curves showing required location of lightning protector tubes, single-circuit pole line

Numbers on curves are minimum distance in feet of guy below bottom arm on unprotected pole

the tube. It must accomplish this protection on the structure upon which it is installed, called the "protected pole," and on adjacent structures called "unprotected poles."

This protection is dependent upon the insulation of the various structure assemblies, the resistance of the tube grounds, and the distance between the tube installations. These conditions were taken into account, both for the protected and unprotected poles, in determining the required location of tubes as given on the following curves.

Figure 5 is for a single-circuit line and shows the allowable distance between protected poles as dictated by the ground resistance of the tube grounds and the location of guy attachments. Since guy locations are determined by local field conditions a family of curves is included to provide for the pole in the section, between protected poles, having the least insulation to ground. As mentioned previously, the clearance strap is installed on the protected pole in order to increase the insulation between the tube ground and the protected phase wires. This strap is not always necessary as indicated by the dotted line on figure 5. For example no clearance strap is needed if the ground resistance is below 24 ohms or if there is an unprotected pole in the section which requires a guy as close as two feet below the bottom arm.

Similarly figure 6 gives data for a double-circuit line based upon the use of a clearance strap on all protected poles. Because of the protected-pole limitation there is no advantage in attaching guys on the unprotected poles more than two feet below the bottom arm.

Two years' operating experience with this type of lightning protection has confirmed the conclusions given in the paper presenting the original design.[2] At the present time it is planned to rebuild an additional 90 circuit miles in 1940 to be in operation for the coming lightning season so that further experience will be obtained.

Discussion

E. Piepho (The Detroit Edison Company, Detroit, Mich.): The authors have presented a good case for lightning protection on wood-pole transmission lines using protector tubes on a high-shielding phase wire. However, reduction of lightning tripouts alone will not justify the expenditure for this type of protection in all cases. Other factors such as maintenance expense, the number of actual service interruptions occasioned by lightning tripouts as compared with tripouts due to other causes, duration of service interruption, etc., must be fairly evaluated. In cases where the line serves as a tie in the transmission network, its opening will not necessarily result in a service interruption and is, therefore, of small consequence if it can be immediately reclosed. Generally speaking, lightning damage does not prevent reenergizing the line within a minute or less, so that even when service interruption occurs it is of short duration. Interruptions due to wind, trees, equipment failure, or public interference, while not very frequent, are much more likely to hold the line out for a considerable time.

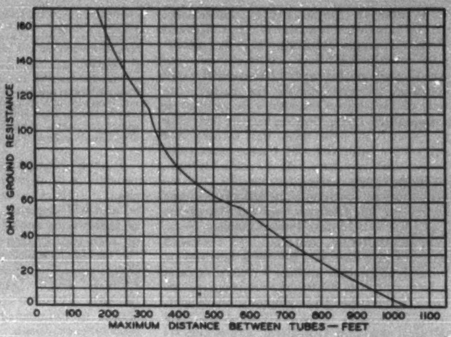

Figure 6. Curves showing required location of lightning protector tubes, double-circuit pole line

On The Detroit Edison Company 24-kv system the five-year operating record for 1,000 miles of overhead lines shows an average of 28.5 lightning tripouts per 100 miles per year. Of this number, 10.5 lightning tripouts per 100 miles per year caused service interruptions of five minutes or less, and only one caused a service interruption exceeding five-minutes' duration. This latter figure compares with 1.4 service interruptions exceeding five minutes due to other causes previously mentioned. It is doubtful whether tube-arrester protection can be justified for the entire system to eliminate so few service interruptions due to lightning, although in the case of a few lines the application of protector tubes appears to be a good investment. Three such lines were equipped with protector tubes in 1939, the selection having been based on line maintenance cost due to lightning, and the importance of the service supplied by the line.

In addition to this protector-tube application, tube arresters were installed on 24-kv pole-top switches in 1938. One-hundred-forty switches were selected for this protection, the selection having been determined by the past operating record of these switches with respect to lightning damage. During the 1939 storm season this protection functioned at an average rate of 1.3 times per switch protected. Only one switch suffered damage due to failure of the tube arresters. This was caused by failure of the protector tube to clear follow current due to excessive tube erosion, which may have been caused by multiple or continuing lightning strokes.

These tubes were inspected last autumn and several removed because of excessive erosion. It appears that isolated installations of protector tubes such as these result in more rapid erosion than has been reported for installations of tubes distributed along a line.

Two protector tubes were found with their bores partly plugged by mud and foreign material such as used by wasps. It is possible that such obstructions may account for the ruptured tubes reported by some users.

H. P. Sleeper (Public Service Electric and Gas Company, Newark, N. J.): Because of the economics involved, open-wire wood-pole transmission-line construction has constituted in the past, and probably will continue to constitute in the future, the bulk of high-power transmission systems in this country. For that reason the lightning protection of such lines has formed the subject of innumerable papers presented before this Institute. It is probably safe to predict that means for combatting this problem will continue to accumulate in the records of this Institute and the files of the United States Letters Patent Office.

It is, therefore, refreshing to review a paper which does not invent a new device but which merely applies an old one in a novel manner to secure improved operation. Such is the subject of the paper on "Lightning Protection of Wood-Pole Lines" by Messrs. Sels and Gothberg, and if the results quoted are any indication of the expected performance, it would seem that the operating results should be meritorious and the economics very favorable.

A study was made by this discusser in connection with the transmission system described by the authors to determine whether the scheme described in this paper, or a Petersen coil, should be applied to improve operation. A study of faults was made from oscillographic data obtained over a considerable period of years. The type of transmission construction involved consisted of a triangular arrangement of phases with two phase wires on top and a 36-inch spacing.

Obviously this construction favored the occurrence of short circuits due to lightning. The cable portion of the complete transmission system constituted 30 per cent of the total mileage. Results over a five-year survey showed that 80 per cent of all faults occurred on the open wire and bus sections of the system, and 20 per cent on the cable section. Furthermore, only 21 of the 80 per cent open-wire and bus faults started to ground. As a matter of interest, 16 of the 20 per cent cable faults started to ground. Hence it was apparent that the 21 per cent of all faults was all that could be eliminated by any scheme of ground-fault extinction. Hence if 90 per cent correct operation were granted to either Petersen-coil operation or expulsion-tube operation, it would still leave 80 per cent plus faults to be relayed out. On this basis the installation of a Petersen coil was not considered economically justifiable. On a program of gradually rebuilding the transmission lines, however, the preferred construction as shown in the authors' paper was practically as cheap as any other and the full effect of the expulsion-tube operation could be obtained at once on the rebuilt lines. On that basis the protective-tube scheme was approved.

This scheme of open-wire transmission construction has distinct advantages:

1. All single-phase-to-ground faults should be extinguished in not more than one cycle of arcing time. In this feature it should compare directly with the operation of a Petersen coil.

2. It should not affect in any way the operation of existing protective relays on the lines. If relays are in use which will respond to short-circuit impulses of one cycle or less, as is the case on the system in question, it will be necessary to delay the tripping of the breaker for that length of time to avoid incorrect operation during the time of tube operation. A scheme for doing this was described by me in the past and is published. (See page 292, ELECTRICAL ENGINEERING, 1938.) The same is true of a Petersen-coil installation.

3. With a high-impedance system neutral in use, as the 75 ohms in the neutral of the system described by the authors, the duty on the tubes does not increase with changing generating capacity in service due to time of day or changing load growth with the years. To a certain degree only, this is also true of a Petersen-coil installation.

Probably the greatest contribution to the continuity of service to the customers of electric utilities today and in the near future is, and will continue to be, the installation of fault-extinguishing devices of some kind on high-voltage transmission lines. Today the two types which have been compared in these comments present interesting possibilities, and existing systems, and particularly systems constructed hereafter, should be capable of capitalizing on their proved capabilities. If a choice must be made as to which system to employ, a study of each individual case seems to be the only answer. If existing line construction is considered satisfactory, or if major reconstruction is not to be made, the Petersen coil will, in this commentator's opinion, prove to be the cheaper to install and maintain. However, it is this writer's opinion that serious consideration should be given to the installation of both types of protection on a given system for the following reasons:

1. The duty on the expulsion tubes would be reduced and longer life should result.

2. Smaller tubes could be used on high capacity systems because of the reduced recovery voltages.

3. Ground faults on busses would be extinguished, which is not accomplished by tubes. This should make the installation of bus differential relay protection unnecessary, except on the very most important busses, since almost all bus faults originate to ground. The economics of this possibility may be paramount.

L. E. Merrow (Rockland Light and Power Company, Nyack, N. Y.): The Rockland Light and Power Company, after considering protection to about 90 circuit miles of 33-kv delta transmission lines of both wood-pole and steel construction, installed a Petersen coil last spring. The territory covered by these lines is north of Public Service Electric and Gas Company, which is above the New Jersey-New York border and has about the same amount of lightning.

Since the coil was installed over 60 per cent of the line disturbances were caused by lightning and 52 per cent of these were extinguished by the action of the coil. The remainder of the disturbances causing trip-outs were either phase-to-phase or two-phase-to-ground. Since some of the wood-pole lines have flat construction, many of the phase-to-phase short circuits occurred on these lines. It is possible, however, that if these particular lines had been protected by rebuilding each pole as suggested in Mr. Sels' paper, the operation of the coil might have been more satisfactory.

F. Von Voigtlander (The Commonwealth and Southern Corporation, Jackson, Mich.): The authors, following the earlier paper on this subject by A. W. Gothberg and A. S. Brookes, present interesting and valuable data on the development of the idea of converting one conductor of a line into a combination phase and shielding wire.

The writer would like to ask to what extent this combined phase and shielding conductor has provided direct-stroke protection for the line such as might be evidenced by reduction in structural damage due to lightning.

The double-circuit construction shown in Figure 4 appears to employ quite conventional spacing and is similar to the design proposed in the 1937 paper. The single-circuit construction as shown in figure 3, however, places the shielding conductor at a considerable height above the other two and in this respect departs markedly from the conventional as well as from the previous proposed design. What factors led to the adoption of the present single-circuit design?

Whenever the use of the conductor as a combination shield wire is proposed, the treatment of the transpositions must be given consideration if the possibility of two-phase-to-ground faults is to be avoided. Various schemes have been proposed to meet this problem. What features have the authors incorporated in their design to take account of the presence of transpositions in the protected line?

E. J. Allen (General Electric Company, Pittsfield, Mass.): The paper by Messrs. Sels and Gothberg is a valuable addition to the field experience with protector tubes, particularly since it describes a substantial application of protector tubes on the top phase or phases only.

This scheme of protection is fundamentally the same as that for the overhead ground wire, since under impulse conditions the top protected phase acts as an overhead ground wire by discharging through protector tubes to ground. Hence, the same fundamental requirements apply as to adequate shielding to unprotected conductors, low ground resistance, and sufficient clearance at mid-span, which govern overhead-ground-wire practice.

Since other operating companies may wish to consider lightning protection of lines by protector tubes on top conductor only, the curves figure 1 of this discussion have been prepared to show the allowable stroke current (two microseconds to crest) through different ground resistances at the protected structure with various impulse flashover values from ground wire to shielded phase conductors. This is based upon the flashover formula[1] described in the appendix of this discussion. A coupling factor of 0.22 was used which appears to be reasonable for the cases presented by the authors, and the relatively negligible effect of normal-frequency voltage was neglected.

Table I was based on 250-foot separation of protector-tube installations, corresponding to tubes on the top phase only at every structure if the span length is 250 feet; or a tube at every other structure if 125-foot spans are used. With the 250-foot separation of protector tubes and two-microsecond lightning-current front, reflections from adjacent protected structures will reduce the voltage and if flashover to shielded phase occurs, it will occur at approximately two microseconds for a stroke between protected structures and at

2 to 3.5 microseconds for stroke to protected structure.

Figure 1 enables analysis under two conditions:

(*a*). Stroke between protected structures

(*b*). Stroke to protected structure

The curves, figure 1, show the advantage of wood crossarm braces and the clearance straps on lower phase (or phases) of protected structures to increase the impulse insulation as described in the paper. For example, for stroke to the protected structure (solid curves) with currents not over 30,000 amperes, an increase in the insulation flashover of shielded conductors from 200 to 400 kv permits ground resistances of 25 ohms instead of 10 ohms. If the flashover level is but 200 kv and ground resistance 25 ohms, the protection would be had for lightning currents up to only 15,000 amperes.

Where the advantages of protector tubes having high discharge current capabilities of 100,000 amperes are to be fully realized, both the effect of high insulation of shielded conductors and low grounding resistance must be utilized if protector tubes are applied to top phase or phases only. For example, for strokes to protected structure of 100,000 amperes, the ground resistance required to prevent flashover of 400 kv lower-phase insulation is 5.5 ohms.

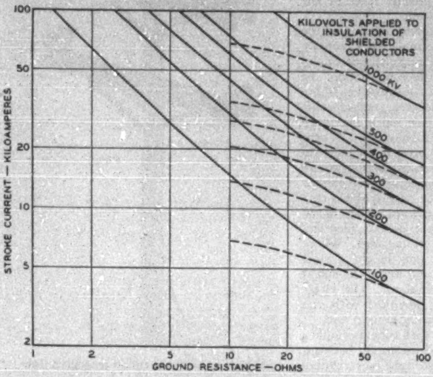

Figure 1. Effect of stroke current upon potential applied to insulation of shielded conductors for various ground resistances of protected structure

Two-microsecond front, protected structures 250 feet apart

Solid curves—Stroke to protected structure

Dashed curves—Stroke between protected structures

The dotted curves, figure 1, show the similar relationships when a stroke occurs between protected structures. As the authors point out, where intervening unprotected structures do exist, use should be made of available wood insulation between line insulators and ground, eliminating any grounded objects at the top of the structure, as for example, guy wires or down leads to ground. For example, a structure of the type shown in figure 3 of the paper not having a protector tube or a down lead to ground would have a higher flashover voltage *V*(*t*) owing to the longer flashover path from top phase to shielded phases. This voltage (dotted curves) should be used in figure 1 when considering the stroke as occurring between protected structures. Where there are no intervening unprotected structures, as for example, a protector tube at each structure, the impulse voltage to cause mid-span flashover corresponds to the air strike distance between conductors at mid-span.

In the example previously considered, where the shielded conductors of a protected structure had a line-to-ground flashover of 400 kv and a ground resistance of 25 ohms, an intervening unprotected structure without down leads may have a line-to-line flashover of 500 kv or more. If the flashover level is 500 kv, the dotted curve shows protection would be afforded the shielded conductors up to 28,500 amperes for 25-ohm ground resistance as compared to 30,000 amperes permissible stroke current to protected structure. By increasing the insulation level between protected structures, this has the advantage of making the line capable of withstanding stroke currents of the same order of magnitude at mid-span as at the protected structure.

The maximum stroke currents which can be permitted at and between protected structures, obtained from figure 1, can be referred to a curve showing frequency of occurrence of various lightning current magnitudes in service.[2] From this the percentage of strokes which the line can handle without flashover can be obtained.

In the two cases investigated, strokes between and at protected structures were considered separately and methods given for estimating them. Actually, however, the stroke may hit the line at any point. Since the nature of the problem hardly justifies a separate investigation for each point on the line where the lightning may strike, it can be assumed, on the average, any stroke within a quarter of the distance of separation between protected structures will be equivalent to a stroke at the structure with the solid curves figure 1 applying, while strokes within similar distance from a mid-point between protected structures are evaluated by the dotted curves, figure 1.

Where protector tubes are applied on all three phases, the protection afforded is independent of ground resistance, the latter values are important only in so far as they affect the single line-to-ground power follow current during tube discharge, and the selection of the minimum-current interrupting rating of the protector tube.

Table I of the paper shows in 1938, 105 operations of the 341 installed tubes were recorded, or 30.8 per cent. The tube operations were 5.7 per mile per year. In 1939, 108 operations of 830 tubes installed were recorded, or 13 per cent, corresponding to only 1.8 operations per mile per year. The total thunderstorm line days, however, had increased to 215 (1939) as compared with 150 thunderstorm line days during the preceding year. The variability between the number of operations of protective devices and the number of thunderstorm days is not unusual. It may be partially accounted for, however, if the storms experienced in 1939 were localized over a small zone of the 59.4 circuit miles of line where protector tubes were installed.

APPENDIX

The flashover formula derived by Bewley is:

$$V=(1-C_n)aR'I+e$$

in which

V = voltage across the insulation

C_n = coupling factor (depends upon the number, configuration, and spacing of the conductors, and is modified by corona)

a = crest factor (depends upon the length of spans or the distance between protector tubes, structure footing resistance, lightning wave front, and conductor surge impedance)

R' = effective resistance (depends upon the grounding resistance, and the surge impedance of the lightning stroke and of the stricken conductors)

I = lightning current which the stroke could deliver to a zero-resistance ground (which is equal to twice the traveling-wave current in the stroke)

e = effective instantaneous normal-frequency voltage (depends upon the normal-frequency polarities and the conductors involved)

H. N. Ekvall (Philadelphia Electric Company, Philadelphia, Pa.): The paper by Messrs. Sels and Gothberg describes a very interesting application of protector tubes to 26-kv wood-pole lines and indicates that it has effected a reduction in line outages of 80 per cent and better. It should be noted, however, that in applying this scheme the insulation strength of the wood-pole lines was materially increased by changing to high ridge pin and twin vertical wire configurations, replacing metal with wood braces and relocating guys.

Experience on approximately 600 miles of 13- and 33-kv wood-pole lines of the Philadelphia Electric Company during the past five years indicates that such increases in the wood insulation strength alone (without application of protector tubes) can effect large reductions in trouble. For example, on 13-kv lines, changeover from flat-top to ridge-pin configuration, relocation of guys, and use of wood braces to take better advantage of the wood-pole insulation have been largely responsible for an 89 per cent reduction in line interruptions per 100 circuit miles during the period 1935 to date. Similarly good performance has been obtained on the 33-kv lines.

The principle of protection employed by the Philadelphia Electric Company is to minimize the formation of power arcs following lightning flashover by increasing the length of wood insulation between phases and between phase and ground up to certain minimum values. This principle of protection has proved effective as indicated above. Power arcs are the chief source of trouble, while lightning itself seldom causes more than slight splintering on the pole or crossarm.

Based on the Philadelphia Electric Company operating experience, it is estimated that the protected 26-kv lines referred to in this paper would have shown a reduction in outages of the order of 80 per cent due to their increased insulation alone, with protector tubes and ground wires omitted. It appears, therefore, that much of the benefit to line performance probably comes from the increased insulation and that a small improvement may come by addition of the protector tubes.

The authors indicate that it is planned to rebuild an additional 90 miles of line in 1940 with increased insulation and protector tubes. In order further to verify the benefits of wood insulation referred to above, it is suggested that on some of the rebuilt lines the ground wires and protector tubes be omitted. This will permit a comparison of the performance of high insulation with and without protector tubes.

Edward Beck (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Messrs. Sels and Gothberg are to be congratulated on at least two counts. Two years ago one of the authors in collaboration with Mr. Brookes published a paper in which the use of one phase wire equipped with tubes was proposed as a ground wire for the circuit. This in itself was a departure from usual practice, and the authors are to be complimented for their initiative in risking the innovation. But further than this, they made calculations two years ago and predicted a reduction of 75 per cent in lightning outages. This was a bold statement at the time. That it was carefully considered and based on sound logic is indicated by the fact that their predictions have more than been fulfilled. We note, however, that now they are more conservative and are careful to state that they do not expect the 100 per cent record to continue. It would add to the completeness of the paper and thus to its value, if the data and premises on which the curves of figures 5 and 6 are based were reproduced also.

The first paragraph mentions about ten times as many line tripouts on the wood 26-kv as on the steel 132-kv circuits. The ground-wire protection on the 132 kv, no doubt, makes much difference. The paper illustrates that a high degree of immunity to lightning outage can be achieved either by proper ground-wire or tube application.

This paper and the one of two years ago together constitute a good example of the solution of a lightning problem by applied engineering.

G. E. Dean (Public Service Electric and Gas Company, Newark, N. J.): In discussion of the paper by Messrs. Sels and Gothberg, I wish to present some of the aspects of field application.

The 26-kv wood-pole transmission of the Public Service Electric and Gas Company contains many miles of single-circuit single-crossarm flat-configuration construction. In order to adapt the new configuration where one phase wire is elevated, considerable rearrangement of the pole top is necessary in addition to the relocation of guys. Where sufficient pole height is present the pole-top pin is used. With this construction, where there is no wood insulation between the insulator pin and the tube base, a shield ring is used to lower the breakdown voltage of the tube. The intermediate pole is identical but is without tube or ground wire. Where there is not sufficient pole height a steel pole extension is used and again the shield ring for the tube is required. The intermediate pole is again identical with the omission of the tube and the ground lead.

The shield ring used with tube assemblies where there is no wood insulation between the insulator pin and the tube base reduces the breakdown voltage of the $6^{1}/_{4}$-inch internal gap by redistributing the electrostatic field around the tube. The ring design is simple and rugged, consisting of three legs to support the ring; these legs in turn being welded to a large washer base. The washer of the shield ring fits over the pipe nipple at the base of the tube so that the ring assembly is slipped over the tube base and the tube installed in the normal manner.

Existing double-circuit poles are of either the two-crossarm triangular configuration or the three-crossarm vertical configuration.

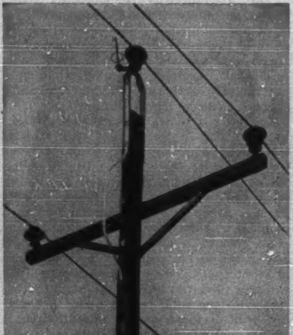

Figure 2. Single-circuit protected pole

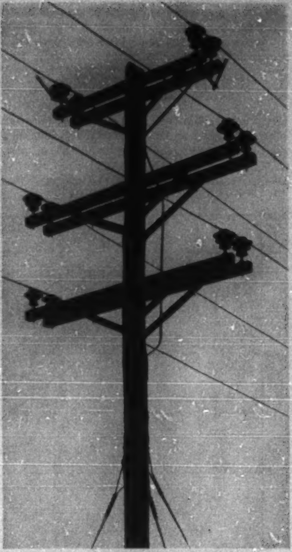

Figure 3. Double-circuit protected pole

Since the new construction is of the three-crossarm type considerable rearrangement may be required. Side guys may be attached to the end of the top crossarm when tubes are used or, in all other cases, must be well below the bottom crossarm. Either the tube or the intermediate pole may of course be double armed for strength requirements without affecting the protection. During the work of the last few years, poles of insufficient height have been replaced with a higher pole but design and test work has been completed on a joint which will permit a wood-pole section supporting one crossarm to be spliced on top of an existing pole. Much of this work will be done during the 1940 program.

Where a tube is installed on a heavy angle pole using suspension type insulators it is necessary to increase the number of insulators on the lower phase wires and attach the guys either to the top of the pole at the tube base or well below the bottom phase. Where no tubes are installed on the corner pole the number of insulators on all phases is increased and the guys must be insulated.

The simplified tube mentioned in the paper consists of the horn fiber tube, itself consisting of concentric tubes of suitable outside diameter to accommodate one-inch pipe threads and the inside, or bore diameter, slightly over one-quarter inch as determined by the 60-cycle phase-to-ground current. The internal gap length is established by choosing a nail of the proper length to give $6^{1}/_{4}$ inches between the end of the nail and the washer at the grounded end of the tube. This internal gap length is of course determined by the flashover characteristics of the insulator to be protected and the recovery-voltage characteristics of the system on which the tube is used. The base of the tube, which is grounded, consists of a straight threaded pipe nipple which is inserted in a hole punched in the mounting strap. A lock washer and nut or nut and lock nut on the nipple below the strap completes the assembly.

It is not expected that this simplified tube will have a life, when exposed to the weather, equal to that of the more elaborate designs. However, the development of the expulsion gap is far from finished and designs have changed so materially that it is not felt necessary to adopt a design of long expected life. The installation of the tubes is made in such a manner that warping of the tube cannot close the external gap and result in the burning of the tube by power current and the tripout of the circuit. It is expected that these tubes will be repainted each three years during the regularly scheduled pole-top inspection.

H. K. Sels and A. W. Gothberg: The authors value the discussions offered and will attempt to close the paper as briefly as possible.

Edward Beck suggests that the data and premises on which the curves of figures 5 and 6 are based should be reproduced also. To include this information would be merely a repetition of a previous paper, reference 2 of the present paper. There have been no changes in the values used as can be borne out by figure 8 in the original paper which corresponds to figures 5 and 6 of this paper. Additional curves were added to figures 5 and 6 to provide for various locations of guy attachments on the poles and also to take advantage of the additional insulation provided by the clearance strap.

The economics of lightning protection is questioned by E. Piepho. It is not suggested that all electric operating companies should rebuild all of their lines to provide this type of protection, but it is felt that if lightning is any problem at all, new lines when constructed can be built to accommodate this protection and the tubes added at any time.

Interruptions of any kind are a hard thing to evaluate. Since transmission is one cog in the electric-utility field there are many associated benefits with this type of protection, such as a reduction in the duty of terminal equipment by lessening the number of tripouts, reducing the number of dangerous overvoltages in stations and adjacent cable sections, improved customer service and its effect on system planning. In considering the necessity of any type of lightning protection the isokeraunic level must be taken into account. There is no doubt that there are some sections of this country where an expenditure for any lightning protection could not be justified. The method of protection proposed is, in the authors' opinion, the most economical to date for the benefits derived and the justification for its economic application depends upon many considerations of the operating company.

E. J. Allen presented a curve, figure 1, showing the effect of stroke current upon the potential applied to insulation of shielded conductors for various ground resistances at the protected structure, with a given distance of 250 feet between protected structures. It will be found by referring to the paper presenting the original design (reference 2) and the results given in figures 5 and 6 of this paper, that they agree very favorably. We wish to thank Mr. Bewley for the time involved to show this agreement and it was upon his original methods that some of our analysis was based and led to the prediction of a 75 per cent reduction in lightning outages.

F. Von Voigtlander has asked to what extent this combined phase and shielding conductor has provided direct-stroke protection for the line as evidenced by reduction in structural damage due to lightning. Two years' experience, with a close examination of all pole tops, has shown no structural damage, indicating 100 per cent shielding effect. As evidence that direct strokes were encountered there were many cases of consecutive tube operations along the line. Anywhere from 5 to 11 tubes have operated in a row. In one particular case in 1938 a tube rated at 100,000 amperes surge current blew up without a line tripout, indicating power current did not cause the damage. In this case all tubes operated in a section of the line for approximately 3,500 feet. Mr. Von Voigtlander also points out that the present single-circuit pole top differs from the one proposed in the 1937 paper. The only difference shown is an additional four inches vertical separation of the shielding conductor above the other two conductors for "minimum" spacing. This change is brought about by a change in pole-top bracket, otherwise the dimensions are the same. The nine feet "normal" distance is used when a single-circuit pole may be converted into a double-circuit pole and the crossarm then becomes the lower crossarm of a double-circuit pole top by the addition of two crossarms and the elimination of the ridge pin. Reference has been made to the question of transpositions but nothing has been worked out to take them into account. Fortunately, low-voltage pole lines are usually short, as is the case of the lines involved in this instance, and no transpositions exist in the lines with this protection.

L. E. Merrow's discussion of his experience with a Petersen coil indicates the necessity of providing a drain point to ground for lightning currents when a coil is used, otherwise many phase-to-phase tripouts will result. This was pointed out in a discussion by one of the authors in AIEE TRANSACTIONS, volume 57, 1938 (December section) page 672.

H. N. Ekvall states that on 13-kv lines of the Philadelphia Electric Company the use of wood insulation has been largely responsible for an 89 per cent reduction in line interruptions and that similarly good performance has been obtained on the 33-kv lines. He suggests that we rebuild some of the lines and omit the protector tubes to show that the increased wood insulation will give an 80 per cent reduction in outages. There is no doubt that the rebuilding of any line by providing more clearances and newer equipment will eliminate many tripouts of all causes. We have tried the use of wood insulation only, exactly as Mr. Ekvall has suggested without the 80 per cent reduction in line outages and found by experience that a good number of the strokes were causing wood splintering. Since this was a source of later trouble wood protector blocks were used in order to direct the wood splintering to a piece of equipment that could be easily replaced. It was then found that these wood blocks would blow up and result in a power arc.

If induced strokes only are to be considered we would agree with Mr. Ekvall but since direct strokes have to be accounted for and putting performance on a basis of outages per 100 miles per year rather than per cent improvement, which depends upon what you start with, we estimate 18 tripouts or cases of damage per 100 miles per year with wood insulation only as compared to 3 tripouts per 100 miles per year with tubes. Generally speaking, we think Mr. Ekvall is getting his protection in the deionizing action of the wood as indicated by the splintering so that the economics of his applying tubes depends upon the damage he is experiencing.

In connection with Mr. Sleeper's recommendations that serious considerations should be given to the installation of a Petersen coil and tubes on the same system, it seems to the authors that the tubes on a Petersen-coil system are entirely unnecessary with protected-phase-wire construction. As pointed out previously, arcing gaps should be provided between the top phase wire and ground to drain the lightning currents from the line. The attention of the manufacturers is called to the necessity for such a device.

We wish to thank Messrs. Dean and Sleeper for their contributory discussions and all of our associates for their share in making this development a success.

The Characteristics and Power Requirements of Spinning Frames—II

E. A. UNTERSEE
NONMEMBER AIEE

THIS PAPER is a continuation of the investigation on the characteristics and power requirements of spinning frames presented at the AIEE North Eastern District meeting, Springfield, Mass., May 3–5, 1939, and published in this volume of AIEE TRANSACTIONS, pages 1–4 (January section).

The original investigation involved a 348-spindle Whitin frame with $1^1/_2$-, $1^3/_4$-, 2-, and $2^1/_4$-inch diameter rings operating at various speeds, and while the analysis indicated very definite characteristics and power requirements, the tests were not sufficiently extensive to conclude that the power formula developed would hold true for larger ring sizes and different-size yarns.

Further tests were therefore conducted on a 216-spindle Whitin frame, with $2^1/_4$-, $2^1/_2$-, $2^3/_4$-, and 3-inch rings spinning 10*s* yarn, and it is the analysis of these tests and their association with the previous tests that is now presented.

In comparing these recent tests with the original tests, it is immediately evident that the $2^1/_4$-inch ring is common to both and that they do not indicate the same power requirement. It is also evident that these two tests were made with different size yarns, and therefore, the formula submitted for the power requirements in the first paper cannot apply, inasmuch as it takes no account of yarn size.

The effect of yarn size on power requirements, other conditions being the same as indicated in figure 1, is definitely a factor to be considered in establishing a formula.

In figure 2, the relationship between yarn size and yarn weight is shown, and since the weight is so small and decreases so gradually in sizes smaller than 20*s*, it is doubtful whether it will affect the power appreciably in this range. In sizes larger than 20*s*, however, the weight increases rather rapidly, and should, therefore, be taken into consideration, but probably 4*s* yarn is about the largest generally made on spinning frames.

In figure 1, which covers the $1^1/_2$-, $1^3/_4$-, 2-, and $2^1/_4$-inch rings on the 348-spindle frame, and the $2^1/_4$-, $2^1/_2$-, $2^3/_4$-, and 3-inch rings on the 216-spindle frame, the power curves have all been reduced to a 216-spindle basis for the purpose of comparison, and in this comparison we have the following data to analyze for the effect of yarn size on power:

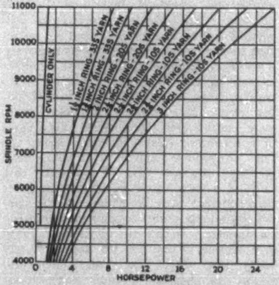

Figure 1. Power requirements of a 216-spindle spinning frame with different diameter rings and various yarn sizes, plotted from formula derived from test data

Ring Diameter (Inches)	Yarn
$1^1/_2$	33*s*
$1^3/_4$	33*s*
2	20*s*
$2^1/_4$	20*s*
$2^1/_4$	10*s*
$2^1/_2$	10*s*
$2^3/_4$	10*s*
3	10*s*

If we analyze each one of the curves separately, the power seems to vary as $(\text{rpm}/1{,}000)^{2.04}$, rpm being the spindle speed.

The spacing of these curves must depend on the ring diameter and the size of yarn, and if we consider frames on which the same size of yarn is spun and run at a fixed speed, it shows the power varies in accordance with 1.42 power of the ring diameter.

The other variable which enters the picture, namely yarn size, is evident in the power curves for the $2^1/_4$-inch rings with 10*s* and 20*s* yarn, and here the power appears to vary in accordance with

$$\frac{1}{\sqrt[4.75]{\text{yarn size}}}$$

from which we may develop the formula for power:

Horsepower per spindle =

$$\frac{0.0003055}{\sqrt[4.75]{S}} \times R^{1.42} \times \left(\frac{\text{rpm}}{1{,}000}\right)^{2.04}$$

where

S = yarn size
R = ring diameter in inches
rpm = spindle speed

Table II has been calculated using this formula. Ring sizes and yarn num-

---

Paper 40-54, recommended by the AIEE committee on industrial power applications, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 24, 1939; made available for preprinting December 18, 1939; released for final publication February 23, 1940.

E. A. UNTERSEE is with the General Electric Company, Schenectady, N. Y.

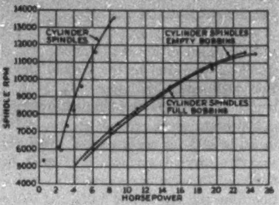

Figure 4. Breakdown test on 216-spindle frame, $2^1/_2$-inch-diameter ring

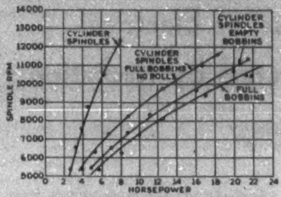

Figure 5. Breakdown test on 216-spindle frame, $2^3/_4$-inch-diameter ring

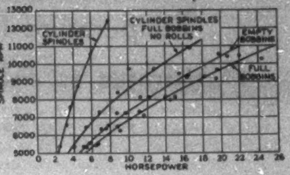

Figure 6. Breakdown test on 216-spindle frame, 3-inch-diameter ring

bers spun in cotton mills vary so widely that no attempt has been made here to cover all conditions, but the figures given will serve as a basis for the more common combinations.

Power readings were taken while spinning yarn at the empty-bobbin position, and again at the full-bobbin position for each diameter of ring, over a range of spindle speeds from approximately 6,000 rpm to 11,500 rpm, the upper range being considerably beyond the point of practical spinning, but as in the previous tests, this was necessary to establish the characteristics of the frame.

Figures 3 and 4 show the power requirements when spinning with $2^1/_4$- and $2^1/_2$-inch-diameter rings, with medium-large spindles.

The power curve for the cylinder and bare spindles is also plotted.

Figures 5 and 6 show the power requirements when spinning with the $2^3/_4$- and 3-inch-diameter rings with the large spindles. It is interesting to note on the breakdown tests on these larger ring diameters that the power required to spin yarn at the empty-bobbin position was considerably more than the power required to drive the spindles with full bobbins, and without the front rolls running. This increase in power is accounted for in the windage and friction of the balloon of the yarn and the traveler.

From the results of both investigations it shows that the cotton-spinning frame

Table I. Spinning-Frame Tests—Frame Data

Type and model—*F*2, long draft
Number of spindles—216
Type spindle—large medium 2*K*, large 4*K*
Whorl diameter—$1^1/_8$ inches
Gauge spindle—$4^1/_2$ inches, four boss rolls
Width tape—$^5/_8$ inch
Traverse—8 inches

Cylinder diameter—10 inches
Cylinder bearings—all ball bearing six-section cylinder
Ring diameter—$2^1/_4$, $2^1/_2$, $2^3/_4$, and 3 inches
Type of ring—number 2 flange
Traveler weight and number—number 10 square point, Bowen
Number yarn spun—10*s*
Yarn spun—warp-filling wind
Ply roving—two ply—1.0 hank. Draft 20. Twist per inch 16.10
Type builder—four-point filling
Thread board—traversing

Diameter front roll—1 inch
Diameter middle roll—$^7/_8$ inch
Diameter back roll—$^7/_8$ inch
Tape idler pulleys—regular; weight used, $2^1/_2$ pounds
Separators—solid aluminum
Weight on front rolls—$4^1/_2$ pounds

Gearing:
- Cylinder—26 teeth
- Jack—112 teeth
- Twist—88 teeth
- Front roll—100 teeth
- Lay—53 teeth
- Crown—140 teeth

Temperature Rise of Electrical Apparatus as Affected by Radiation

G. W. PENNEY
ASSOCIATE AIEE

Synopsis: Radiation is generally of importance only in apparatus cooled by natural convection and radiation. If such apparatus with a smooth exterior surface is mounted in the sun and shielded from the wind, an additional rise as high as 20 degrees centigrade may occur. White or gray nonmetallic paints may decrease solar effects. Fins and corrugations increase the ratio of convected to radiated heat and thereby decrease radiant effects.

IN electrical engineering, radiation is relatively unimportant in the normal application of most apparatus, but in occasional applications it should be considered.

The subject of radiation has received considerable attention from heating and ventilating engineers.[1,2] It is always considered in computing the amount of refrigeration required for air conditioning. In this case, large areas are exposed to sunlight and small temperature differences are important. In the dissipation of heat from the human body, radiation is normally more important than convection and differences of a few degrees in wall temperature are important.[3]

In electrical engineering, motors, transformers, and similar apparatus operate at higher temperatures, so that a difference of a few degrees is not as important as in air conditioning. The effect of radiation on the temperature rise depends on the enveloping area of a device. In most devices the cooling obtained from a smooth surface is inadequate, so that finned or corrugated surfaces, forced air circulation, or water cooling are provided. Under these conditions the normal losses of the device per unit of enveloping area are large, so that the radiant effect of hot walls or the sun is small as compared to the normal losses. For such cases radiation will have a negligible effect on the temperature rise.

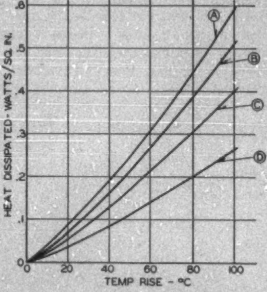

Figure 1. Heat dissipation–temperature rise curves

A—Radiation from black surface to black surrounding surfaces at 25 degrees centigrade

B—Natural convection from a large (two feet or over) surface facing upward

C—Natural convection from a large vertical surface

D—Natural convection from a large surface facing downward

However, some types of apparatus must depend for cooling on a relatively smooth external surface, and may be mounted in locations exposed to radiation from the sun or hot walls. It is the purpose of this paper to point out the relative magnitudes of these factors and to give curves which will be helpful in estimating the temperature rise under unusual circumstances where radiation is important.

Radiation of Heat

The basic law of heat radiation is that any object is radiating heat proportional to the fourth power of the absolute temperature, but all surrounding objects are likewise radiating. If the surfaces are partially reflecting, multiple reflections lead to complicated calculations.

In the case of a sphere or plane surface small as compared to the enclosing space, the heat loss from the small surface becomes independent of the emissivity of the enclosing surface because of multiple reflections within the enclosing

---

has a very definite speed-power characteristic which is not only affected by the number of spindles, but also by the ring diameter and the size of yarn spun. When these conditions are known, it is possible to predict, within reasonably close limits, the power required to drive a spinning frame.

There is a possibility that these machines, like most others, may vary slightly in power requirements even when so-called duplicates are involved. These variations should not affect the horsepower rating of the motors selected to drive the frames, and these data should be of considerable help to the machine manufacturer and the textile manufacturer in selecting the proper-size motor for applying to spinning frames within the scope of these investigations.

space. The heat loss from the small surface is that given by the familiar Stefan-Boltzman law.[15,4]

$$W=36.9e_1\left[\left(\frac{\theta_1}{1,000}\right)^4-\left(\frac{\theta_2}{1,000}\right)^4\right]$$

W^* = energy radiated, watts per square inch
θ_1 = temperature of radiating surface (degrees Kelvin)
θ_2 = temperature of the enclosing surface (degrees Kelvin)
e_1 = emissivity of the small surface

The emissivity of any surface is equal to its absorption coefficient. Also, $1-e=$ reflectivity.

If the radiating object becomes of appreciable size as compared to the enclosing surface, the emissivity of the enclosing surface becomes of importance since, in a reflecting enclosure, radiation from the sphere will be reflected back onto the emitting surface. A. D. Moore[4] has evaluated the heat loss for several typical cases of this type and also the increase in radiation due to grooves or corrugations in reflecting surfaces. Another complication is that in general the emissivity of a surface varies with the wave length of the radiation. For example, white paint reflects a large percentage of solar radiation but is a good absorber for low-temperature radiation. In the case of irregular partially reflecting surfaces, exact calculations are usually too complicated for engineering purposes.[5] Fortunately, most electrical apparatus is painted with a nonmetallic paint which has an emissivity of the order of 0.9 for long wave lengths. The effective surface for radiation is then approximately the same as the enveloping surface. Radiation is in general not of importance in apparatus which is cooled by fans or is water cooled. In dealing with apparatus cooled by natural convection and radiation which must be located adjacent to hot surfaces, it usually is sufficient to compare the relative magnitudes of radiation and convection on the test floor with those calculated for service conditions and from these estimate the temperature under the service conditions. Natural convection varies widely, depending on the shape of the surface and surrounding objects. However, curves are available which give the convection under average conditions, and for many engineering purposes these values will prove sufficiently accurate. Figure 1 compares radiation for 25-degree enclosing walls and convection for large plane surfaces as given by McAdam's equations.[6] Figure 2 gives radiation for several other enclosing surface temperatures. The curves are useful in approximating the temperature rise under conditions near hot walls.

Solar Radiation

The radiant energy received from the sun has been the subject of many careful measurements.[8,9,10] It fluctuates about seven per cent due to variation in the distance of the sun and sun spots. The radiant energy from the sun as it would be measured by an observer at the earth's mean solar distance but outside our atmosphere, is called the "solar constant."

The mean of 692 determinations of the solar constant in the period from 1902 to 1912 gave a value of 1.94 gram-calories per (minute × centimeter square) or 0.87 watt per square inch.[11]

The intensity of radiation as measured at the earth's surface varies over a wide range, depending on the altitude, humidity, and cloudiness. The curves of figure 3 are plotted from values given in the Smithsonian Physical Tables[11] and give the intensity as a function of wave length for various altitudes and angles of the sun from the zenith. These curves apply to conditions of low humidity and no volcanic dust, so that they give practically maximum values of direct solar radiation.

A large portion of the reduction in solar energy in passing through the atmosphere is due to scattering. Much of this scattered energy reaches the earth as "sky light." This has not been studied as extensively as the direct solar radiation. In general, the scattered radiation or sky light is increased as the direct solar radiation is decreased by a longer path through the atmosphere or by increased haziness. Abbot[12] gives a value of sky light on Flint Island (sea level) of 32 per cent of the direct radiation and for Mount Wilson 7 per cent of the direct radiation.

Taking 0.6 as a typical value of direct radiation at sea level, 32 per cent of 0.6 gives 0.19 watt per square inch as sky light. For Mount Wilson 7 per cent of 0.74 gives 0.05 watt per square inch as sky light. The total radiation received by a horizontal surface with the sun at zenith would then be 0.6+0.19=0.79 for Flint Island and 0.74+0.05=0.79 for Mount Wilson. These meager data would seem to indicate that under favorable conditions a surface at sea level may receive nearly as much total energy as at high altitude, and that this value may be as high as 0.8 watt per square inch. Houghten, Blackshaw, Pugh, and McDermott[1] give values of solar radiation

* Watts, inches, and degrees centigrade are generally used in this paper because they are believed to be the most convenient units for the electrical engineer. To convert watts per square inch to Btu per (hour × square feet) multiply by 493; to convert to gram calories per (second × square centimeters) multiply by 0.037.

as measured at the United States Weather Bureau station in Pittsburgh, Pa. Figure 4 gives their values. Their maximum value of radiation is 0.63 watt per square inch. From the data available, the writer considers 0.75 watt per square inch as the typical maximum value of solar radiation (that is, 20 per cent greater than that given by figure 4).

Effect of Solar Radiation on the Temperature of Apparatus

As has been mentioned, most devices having forced air circulation or water cooling, will have a high loss per unit of external projected area exposed to the sun. The heat received from the sun is, therefore, small as compared to the normal losses and has a negligible effect on the temperature rise. Such cases will not be considered further.

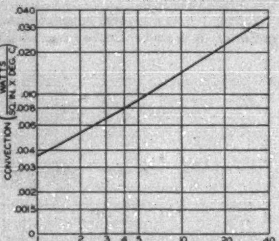

Figure 5. Convection from six-inch-diameter cylinder as affected by air flow perpendicular to axis of cylinder

The heat received by apparatus exposed to the sun can be estimated from data on solar radiation. If all parts of the device can be assumed to be at the same temperature, and if the watts lost and temperature rise under test conditions are known, the watts dissipated per degree rise can be calculated. The additional rise due to radiation from the sun can be estimated.

However, under service conditions, several factors tend to reduce the temperature below that which would be obtained in this way.

1. Large apparatus cooled by natural convection and radiation approaches its final temperature slowly so that the solar radiation will be decreasing before the apparatus reaches its maximum temperature.

2. Most locations exposed to the sun will likewise be exposed to wind which will give a greater loss per degree by convection than that obtained in the test floor.

3. The sky is very seldom cloudless, so that the maximum value of solar radiation is seldom obtained continuously.

Figure 6. Diagram of apparatus for measuring temperature rise due to solar radiation

Apparatus exposed to the sun receives direct and scattered radiation and radiates to the sky. To be strictly accurate in estimating the radiation from apparatus out of doors, the effective temperature of the sky should be used. However, calculations indicate that for apparatus with a surface rise of 50 degrees centigrade or less, such refinements are not justified by the accuracy of our knowledge of scattered radiation and effective temperature of the sky. The term "sky light" has been applied to the net radiant energy received by a black surface exposed to the sky, taking as zero the condition when the black surface is covered by a radiation shield at ambient temperature. Sky light is, therefore, the difference between the scattered solar radiation falling on the measuring surface and the additional heat radiated from this surface due to the fact that it is exposed to the sky rather than to a surface at ambient temperature. Therefore, in this paper the additional temperature rise of apparatus due to solar radiation will be calculated on the assumption that the apparatus receives both direct solar radiation and sky light, and that the apparatus dissipates its heat as though it were radiating to surfaces at ambient temperature.

Figure 5 is a curve of convection as affected by wind velocity. This curve was plotted from a dimensionless curve given by McAdams.[7] From this curve it is evident that a wind velocity of one mile per hour is sufficient to give a noticeable increase as compared to natural convection in still air. A wind velocity of ten miles per hour gives a convection coefficient of 0.014 watt per (square inch × centigrade degrees). At 40-degrees centigrade rise this gives 0.56 watt per square inch, which is 4.3 times the loss by natural convection. Appendix I considers a simplified case of apparatus exposed to sun and wind simultaneously, showing that a wind velocity of four miles per hour is sufficient to compensate for the heat received from the noonday sun.

Another method of reducing the temperature rise due to solar radiation is to use a paint which reflects much of the short-wave-length radiation, but acts as a good radiator for long wave lengths. White paint may absorb only 25 per cent of solar radiation but 95 per cent of long wave lengths. There would be few locations where a clean white surface could be maintained, but a gray paint showing an appreciable gain might be practical. Metallic pigments as in aluminum paint give a high reflectivity for all wave lengths. This reduces the solar radiation absorbed, but also reduces the dissipation of heat by radiation so that the device will usually operate at a higher temperature than if painted black. Montsinger[13] has discussed this question, and has given several typical curves showing the temperature rise of transformers under service conditions. The wind velocity was not reported, so that his values cannot be used to predict the temperature which would occur under other wind conditions.

Test Results

Under many conditions there will be sufficient wind so that the increased convection will compensate for the heat received from the sun. Occasionally there are periods of calm, or apparatus may be mounted in locations where it is shielded from the wind by buildings.

Tests were made to demonstrate the temperature rise which may occur under certain conditions due to solar radiation. Two small (100-watt) transformers were used. To determine any differences in manufacture or position of inserted thermocouples, tests were first run in the laboratory. The temperature rise obtained in the first test is plotted in curves *A*1, *B*1, and *AB*2 of figure 7. This shows that the iron temperature of both transformers was the same, but that the copper of transformer *A* ran about 2 degrees warmer than that of transformer *B*. To be certain that both were loaded equally, the primaries were operated in parallel and the secondaries in series supplying a common lamp load.

To obtain results not influenced by clouds, the field tests were made in Colorado at 38 degrees latitude and at an elevation of 4,200 feet. The first test was made with the transformers supported about one foot above the ground and in a location shielded from the wind by a small building. Transformer *B* was exposed to the sun, while transformer *A* was shaded by a piece of Celotex four feet by four feet supported about two feet above the transformer. The arrangement was similar to that shown in figure 6, except that the test was made on level ground instead of in a pit. The results of this test are shown as curves *A*3 and *B*3 of figure 7. While an attempt had been made to locate the test where it would be shielded from the wind, this was not entirely successful. Especially toward the end of the test, gusts of wind would occasionally give anemometer readings of 75 feet per minute near the transformers. It is believed that the drop in temperature near the end of the test was caused by these gusts of wind. Under these conditions the copper of transformer *B* which was exposed to the sun operated at 17 degrees centigrade greater rise than that of transformer *A* which was shaded, although in the laboratory the copper of transformer *A* had been 2 degrees warmer. The difference due to solar radiation was, then, 19 degrees centigrade.

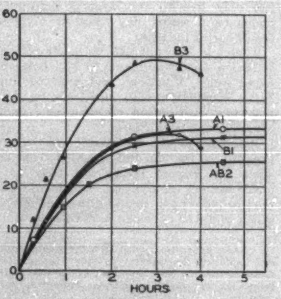

Figure 7. Time–temperature rise curves of small transformers

*A*1—Copper temperature of transformer *A* as tested in laboratory

*B*1—Copper temperature of transformer *B* as tested in laboratory

*AB*2—Iron temperature of transformers *A* and *B* as tested in laboratory

*B*3—Copper temperature of transformer *B* exposed to the sun

*A*3—Copper temperature of transformer *A* shaded

To eliminate the effect of the wind, another test was made in a pit 7 feet deep by 15 feet wide with concrete walls. This test arrangement is shown in figure 6. This time transformer *A* was exposed to the sun and transformer *B* was shaded. As would be expected in a location so well shielded from the wind, the ambient temperature rose considerably. For this reason actual temperatures are plotted rather than temperature rise in figure 8. In this test at the end of $2^1/_2$ hours the copper of transformer *A* was 22 degrees warmer than that of transformer *B*. Correcting for the 2-degree difference in the laboratory test, the rise due to radiation would be 20 degrees centigrade. The effect of solar radiation on iron temperatures was to give an additional rise of $20^1/_2$ degrees centigrade. An approximate calculation of temperature for this case is given in the appendix.

To illustrate one unusual condition, a piece of blackened sheet copper was mounted on $1^1/_2$ inches of thermal insulation (wood-pulp packing material). In this way the loss from the back of the sheet metal was small and the area for dissipating heat by convection was the same as the area exposed to radiation. With an ambient of 40 degrees centigrade the sheet metal attained a temperature of 90 degrees centigrade. To illustrate the effect of possible reflections, a piece of dull tinned copper was set up as a reflector as shown in figure 6. This increased the temperature of the blackened metal to 109 degrees centigrade. Or course, many other special tests could be made showing still higher local temperatures. Apparatus under a glass cover gets very hot because most glasses transmit solar radiation efficiently, but are opaque to long wave lengths, so that apparatus under glass receives solar radiation but cannot be cooled by radiation through the glass. Almost everyone is familiar with the use of a lens or parabolic mirror to produce fire, which is an extreme example of high temperature resulting from solar radiation.

Summary

In apparatus with a smooth exterior surface and without fans or liquid cooling, radiation to surrounding objects is usually more important than convection. In this case, the surface temperature of surrounding objects may be more important than the air temperature.

Solar radiation on clear days may be as high as 0.8 watt per square inch of surface normal to the sun.

The effect of solar radiation on the temperature rise of apparatus with forced air circulation or water cooling is generally negligible.

If apparatus cooled only by natural convection and radiation from a smooth surface is exposed to the sun but shielded from the wind, additional temperature rise may be of the order of 20 degrees centigrade. However, a wind velocity of a few miles per hour can compensate for the solar radiation. The effect of solar radiation can be decreased by white or gray paint.

High local temperatures can result from unusual conditions, a common example being an object with a glass cover. An extreme example is the high temperature at the focus of a parabolic mirror or lens.

Appendix

Approximate calculations are given for two smooth-exterior, self-cooled devices showing the additional temperature rise resulting from exposure to the sun in still air, and the effect of a slight wind on the temperature rise.

A. Calculations for 100-Watt Transformers Used in Tests

Under laboratory conditions the transformer case operated at an average temperature rise of 21 degrees centigrade. The total surface area was 81 square inches. Using the curves of figure 1 in approximating the heat dissipated from the case gives, in watts per square inch,

Convection loss	0.055
Radiation ($e=0.95$), $0.092\times0.95=$	0.087
Loss by radiation and convection	0.142

$0.142\times81=11.5$ watts total heat dissipated, which compares with measured losses of 12 watts

When operating in the sun, the total solar radiation from the curves of figure 4 give 13.8 watts at 9 a.m. This value is obtained by multiplying the projected horizontal area by the value per square inch for a horizontal surface from curve *B* of figure 4; the east area by the value given by curve *C*, etc. At 10 a.m., the radiation was 14.2 watts; at 11:00, 13.3 watts, and at noon, 11.6 watts. Averaging these values gives 13.3 watts as the average heat from the sun, which would be received by a perfect black body. The value of emissivity was assumed to be 0.95. The curves of figure 4 were obtained from the weather-bureau station in Pittsburgh, Pa. From the data available, the values for Colorado are probably 20 per cent higher.

Correcting the above average in this way gives

$13.3\times0.95\times1.2=15$ watts

as the estimated average solar radiation.

Adding this to the 12 watts electrical losses gives 27 watts, or 0.33 watt per square inch. By trial and error, using figures 1 and 2, we find that 40-degrees centigrade rise gives, in watts per square inch,

Radiation (40-degree surroundings)
$0.23 \times 0.95 = 0.205$
Convection loss 0.126

Total 0.331

This gives an additional surface rise of $40 - 21 = 19$ degrees centigrade. The drop from copper and iron to the surface is not changed, so that all temperature rises should be 19 degrees higher than in the shade, which compares with $20^1/_2$ degrees centigrade in the test values given by figures 7 and 8.

B. Effect of Wind

To illustrate the effect of the wind, assume that some device (for example, a transformer) in a cylindrical case six inches diameter by ten inches high is mounted on a pole. Assume the case is smooth and at a uniform temperature. Calculating the solar heat input by considering as before the horizontal, east, south, and west projected areas and the corresponding values of radiation, gives an average heat input from 9 a.m. to 12 noon of 39.5 watts or

$\frac{39.5}{244} = 0.162$ watt per square inch of total surface

Assuming that the normal surface rise is 30 degrees centigrade above an ambient of 25 degrees centigrade gives a heat dissipation of

Convection loss 0.085 watt per sq. in.
Radiation $0.135 \times 0.95 =$
0.128 watt per sq. in.

0.213 watt per sq. in.

0.213×244 square inches = 52 watts normal dissipation
$0.213 + 0.162$ sun effect = 0.375 watt per square inch

to be dissipated when exposed to the sun. By trial and error from figure 1

47 degrees centigrade rise gives
Convection loss 0.155 watt per sq. in.
Radiation 0.23×0.95
0.22

0.375 watt per sq. in.

We would then expect this device to operate at 17 degrees centigrade additional rise if exposed to the sun with no wind.

A wind of four miles per hour gives from figure 5 a heat dissipation of 0.008 watt per (square inch × centigrade degrees). At 30-degrees centigrade rise, this gives

0.24 watt per square inch convection loss
$0.135 \times 0.95 = 0.13$ watt per square inch radiation
$0.24 + 0.13 = 0.37$ total

In other words, a wind of four miles per hour would increase the convection by an amount equal to the heat received as solar radiation, so that the temperature rise in the sun would be the same as on the test floor.

A wind of ten miles per hour would give a convection coefficient of 0.014 watt per (square inch × centigrade degrees). At 21 degrees centigrade rise this gives

Convection loss $(0.014 \times 21) =$
0.294 watt per square inch
Radiation $0.095 \times 0.95 =$
0.09 watt per square inch

0.384 watt per square inch

Therefore, a wind of ten miles per hour would dissipate the heat at 21 degrees centigrade rise, or 9 degrees centigrade below normal.

Discussion

M. F. Beavers (General Electric Company, Pittsfield, Mass.): This paper presents some very interesting test data on the effect of solar radiation and wind on the thermal characteristics of small transformers compared to the characteristics under laboratory conditions.

Mr. Penney concludes among other things in his summary that "If apparatus cooled only by natural convection and radiation from a smooth surface is exposed to sun but shielded from the wind, additional temperature rise may be of the order of 20 degrees centigrade. . . ."

This certainly should be a warning to avoid installing small transformers with smooth surfaces in a location shielded from the wind but exposed to the sun for the major part of the day. It is probable that a small percentage of installations fall into this class.

On the other hand, it should not be alarming to those who have made tests or obtained reports to the effect that the temperature rise over ambient of an ordinary oil-immersed pole-type distribution transformer, under actual service conditions, will run only five to ten degrees centigrade higher on a sunny day than on a cloudy day or during the night.

Therefore I would like to recall to your attention some statements in Mr. Penney's paper which, I believe, will tend to show better correlation with previous tests on pole-type distribution transformers under actual service conditions.

Referring to the additional rise due to exposure to the sun but shielded from the wind, Mr. Penney points out that ". . . under service conditions, several factors tend to reduce the temperature below that which would be obtained in this way.

> "1. Large apparatus cooled by natural convection and radiation approaches its final temperature slowly so that the solar radiation will be decreasing before the apparatus reaches its maximum temperature.
>
> "2. Most locations exposed to the sun will likewise be exposed to wind which will give a greater loss per degree by convection than that obtained in the test floor.
>
> "3. The sky is very seldom cloudless, so that the maximum value of solar radiation is seldom obtained continuously."

Item number 13 in Mr. Penney's bibliography refers to an article by Montsinger and Wetherill entitled "Effect of Color of Tank on the Temperature of Self-Cooled Transformers Under Service Conditions" in which the results of various tests on distribution transformers located outdoors under normal weather conditions are given.

Table I

Color of Tank	Oil Temperature Rise—Deg C (1) Min.	(1) Avg.*	(1) Max.	(2) Min.	(2) Avg.*	(2) Max.	(3) Min.	(3) Avg.*	(3) Max.

(1). Transformer without excitation or load (idle).
(2). Transformer with normal excitation only (no load).
(3). Transformer with normal excitation and normal load.
* Average temperature rise over a 24-hour period.

Figure 1 of the Montsinger-Wetherill paper shows a chart of oil temperature and ambient air temperature for a period of two days for four 5-kva transformers under excitation only (that is, no load). Two of the transformers were in black-painted tanks, one was white, and one was aluminum painted (tests were made in Pittsfield, Mass.).

In order to show the effect of the sun on the transformers in the black-painted tanks I analyzed the oil temperature rise over ambient air for the two-day period from August 12 to 14, 1909. The average minimum oil rise of 7 degrees centigrade occurred in the neighborhood of 4 a.m. to 8 a.m. and the maximum oil rise of 14 degrees centigrade occurred at 6 p.m. The additional rise due to the sun, then, is $14-7=7$ degrees centigrade.

With reference to the temperature of the transformers in the white and aluminum-painted tanks Montsinger states ". . . that the transformer with the black tank averages one to two degrees centigrade hotter than the one with the white tank. . . . The temperature of the aluminum-painted tank was as a rule between those of the black and white tanks."

Tests made on several 3-kva lighting transformers in August and September 1922, by Messrs. Moore and Moulton of the San Joaquin Light and Power Corporation are reported in this reference and are summarized in table I of this discussion.

An analysis of the data from which this summary was taken indicates that the maximum oil rise occurs in the vicinity of 6 to 8 p.m. and the minimum oil rise occurs during the early part of the morning with very little increase in rise before 10 a.m.

The additional temperature, then, due to the sun, is the difference between the minimum and maximum oil rises observed.

For the Moore-Moulton tests the maximum difference is 9.5 degrees centigrade, on the transformer in the black tank under normal load and excitation.

In regard to the benefits of the gray paint Moore and Moulton concluded that "We have reached the conclusion, after a very careful study of the results herein recorded, that any additional expenditure to procure a gray case instead of black would not be justified."

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): I wish to discuss the curves given in figures 1 and 2 of Mr. Penney's paper. In my work I have used curves or equations quite similar to those used by the author. For example: I have used 36.8 for the constant in the radiation formula, and 0.95 for the emissivity factor e_1 for all surfaces painted with nonmetallic or pigment paints.

The equation of curve *C* in figure 1 for loss of heat by convection from a large vertical surface appears to be, $W_c=1.265\times 10^{-3}\ \theta^{1.25}$, where W_c=watts per square inch and θ=temperature rise in degrees centigrade. I have used the same form of equation but with a constant of 1.4×10^{-3} which gives approximately ten per cent more loss by convection than curve *C* gives for the same temperature rise.

The curves in figure 1 show that the percentage of losses from a large vertical surface are approximately 60 per cent by radiation and 40 per cent by convection at 25 degrees centigrade. I have found approximately 55 per cent and 45 per cent respectively, the difference being due to the difference in the constants used in the convection formula. This ratio changes with room temperature, since loss of heat by radiation increases with increasing room temperatures, whereas loss by convection is practically unaffected by changes in room temperature. An easy rule to remember is that loss by radiation increases from 1.0 to 1.2 per cent for each degree increase in the room temperature. This is shown by the curves in figure 2. For example: for 60 degrees rise the ratio of the losses in a 100-degree room and a 25-degree room is (0.57/0.30):1.9. That is, the loss is 90 per cent more in a 100-degree room than in a 25-degree room. 90 per cent divided by 75 degrees gives 1.2 per cent increase per degree. For 80 degrees rise the difference between the 40 and 100-degree curves is one per cent per degree. The average value is approximately 1.1 per cent.

For limited temperature rises—up to about 75 degrees—it is possible to approximate closely loss of heat by radiation at various room temperatures by a simple logarithmic equation, as is shown on page 272 of the book on "Transformer Engineering". The equation is:

$$W_r=1.84\times10^{-3}\theta^{1.10}E\left(1+\frac{1.1\theta_a}{100}\right)$$

where

W_r = watts per square inch
θ = temperature rise degrees centigrade
E = emissivity factor
θ_a = room temperature degrees centigrade

Referring again to loss of heat by convection, it should be kept in mind that the constants mentioned before apply only to large vertical surfaces of approximately two feet height and more. For short heights, the constant increases. Some investigators state that the loss varies inversely as the height raised to the one-fourth power. For example: if the loss is unity for a 24-inch height, for a 2.4-inch height the loss would be $(24/2.4)^{1/4}=1.78$ or 78 per cent more watts per square inch for the same temperature rise. I would like to ask Mr. Penney if he took the height of his 100-watt transformer into consideration when evaluating the ratio of losses by radiation and convection. If not, I am inclined to believe that the effect of the short vertical surface of the 100-watt transformer on the loss by convection was much more than the effect of the low wind velocity.

Referring to my paper—reference 13—as Mr. Penney surmises no record was made of the wind velocity when the field tests were made. The conditions under which the several tests were made correspond to those under which transformers operate in service. As all the tests indicated that the effect of the color of the tank on the relative temperature rise was quite small, two degrees centigrade at the most, it is felt that the conclusions drawn were sound, namely, that the question of the kind of paint used on distribution and power transformers exposed to the sun's rays, is one of appearance and durability only.

R. E. Hellmund (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Penney's paper gives some very important practical as well as theoretical information on the effects of radiated heat on apparatus. In addition to apparatus intended for outdoor installation, apparatus designed for indoor use is frequently installed outdoors in enclosures of some kind or other. From Mr. Penney's paper it would seem that if these enclosures are ventilated, the sun radiation will have little influence. On the other hand, if the enclosures are not ventilated and if the surface of the enclosure is much larger than the surface of the apparatus enclosed, conditions might be different from those of the transformer discussed in the paper. It would be interesting if Mr. Penney could give in his closing discussion some data regarding installations of this kind.

R. E. Hellmund and F. R. Benedict (nonmember; both of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Penney's paper discusses two factors, namely, sun radiation and wind, as affecting temperature conditions of electrical apparatus installed outdoors. It may therefore be appropriate to give some data which have recently become available on outdoor temperatures. In the paper entitled "Temperature Survey of the United States," by J. J. Smith and H. W. Tenney, which was presented at the 1939 AIEE summer convention, some valuable information was given on ambient outdoor temperatures in the United States. It is now generally conceded that the life of insulation is a function of both temperature and time during which certain high temperatures prevail. It is also well known that temperature variations below a certain safe temperature have little influence upon the deterioration of insulation. In view of this, the electrical engineer is interested principally in ambient-temperature conditions in excess of certain values and the time during which they prevail. The information of this nature given by Smith and Tenney covered seven selected typical stations for the period 1934 to 1938 inclusive, and included curves for the average number of hours per year and the average number of hours per day versus the average number of days per year during which the ambient temperature exceeded 90 degrees Fahrenheit. The paper also gave information for three selected stations for the period 1934 to 1939 inclusive, using 105 degrees Fahrenheit as a basis. These data were prepared from records of the United States Weather Bureau.

It is naturally desirable to have similar data from a larger number of stations, and such data have been made available in tables published in *Heating and Ventilating*, March 1939, under the subject "Number of Hours Per Year of High Dry-Bulb Temperatures." These tables give an analysis of 41 well selected and distributed stations. Three tables are shown, as follows:

Table 1. The maximum number of hours in a year that dry-bulb temperature exceeds 85, 90, 95, 100, 105, 110, and 115 degrees Fahrenheit. Maximum in any year from 1932 to 1937 inclusive.

Table 2. The average number of hours per year the dry-bulb temperature exceeds 85, 90, 95, 100, 105, 110, and 115 degrees Fahrenheit. Average for the years 1932 to 1937 inclusive.

Table 3. The minimum number of hours in a year that dry-bulb temperatures exceed 85, 90, 95, 100, 105, 110, and 115 degrees Fahrenheit for the years 1932 to 1937 inclusive.

From these data the number of hours the ambient temperature exceeds 30, 35, 40, and 45 degrees centigrade can be obtained (85F = 29.4C; 95F = 35C; 105F = 40.5C; 115F = 46.1C).

For our problem the data in table 2 are most pertinent because they cover averages for a period of six years. In a study of the deterioration of insulation we are interested not so much in an individual or maximum-temperature year, but in what happens during the entire life of the equipment. A 6-year period gives a pretty good idea of this, as any variations that may exist between a 6- and a 10- or 20-year period are negligible for the problem at hand.

Referring to table 2, we find that the average number of hours per year during which the temperature exceeds 35 and 45 degrees centigrade for the station having the maximum average number of hours above the given temperature is as follows:

Deg C	Hours	Station
30	1,084	Dallas, Tex.
35	292	Topeka, Kans.
40	37	Topeka, Kans.
45	0	

Expressed in percentage of total hours per year (8,760 hours), this leads to table *A* in figure 1 of this discussion.

As will be seen, the maximum hours for a given temperature do not all occur at the same station and thus no individual piece of apparatus is exposed to conditions quite as severe as those indicated in the table. It is therefore quite safe to state that, for our problem, the figures in table *A* represent the "maximum climatic ambient temperatures" in the United States. It may well be contended that the use of the maximum ambient conditions met by all electrical apparatus will lead to poor economy in the application of the large majority of apparatus. Reference to table 2, *Heating and Ventilating*, March 1939 indicates that the stations which are of high average are localized in Texas, Oklahoma, Kansas, Arkansas, and Louisiana. If stations in these areas are eliminated, the station with the maximum average number of hours at the given temperatures will then be as follows:

Deg C	Hours	Station
30	892	Kansas City, Mo.
35	248	Kansas City, Mo.
40	32	Kansas City, Mo.
45	0	

In considering the elimination of some stations or areas, the number of motors and horsepower installed in the various states in which the high-average stations were located, was taken into account. The paper by Smith and Tenney gives sufficient data to show that the elimination of Texas, Oklahoma, Kansas, Arkansas, and Louisiana involves only 3.05 per cent of the total number of motors and 3.9 per cent of the total horsepower installed (probably less than 5 per cent of all electrical apparatus). On the basis of an 8,760-hour year, the predominant climatic ambients for the areas in which over 95 per cent of all electrical apparatus is installed would then be as shown in table *B*, figure 1.

Stated in another way, it would be expected that the ambient temperature would be above 30 degrees centigrade ten per cent of the time or less; above 35 degrees centigrade three per cent of the time or less; above 40 degrees centigrade 0.5 per cent of the time or less; and above 45 degrees centigrade such a small part of the time that for all practical purposes it can be considered as zero.

45	100

It may be of interest to consider only the essential industrial areas of the country. This can be done by excluding North Carolina, Tennessee, and the states south thereof, the southwest corner of Illinois, the states of Iowa and Nebraska and those south thereof, the states Arizona, Nevada, Utah, and New Mexico, and the southeast corner of California. We then find conditions as shown in table *C*, figure 1, for the areas included.

As a matter of course, the values in these tables apply also for any well-ventilated indoor areas where the indoor temperature is about the same as the outdoor. In indoor areas not so well ventilated and in which the electrical and other heat-generating apparatus is small compared with the space available, conditions should be even more favorable. On the other hand, in poorly ventilated indoor areas having a relatively large amount of heat-generating electrical apparatus and other heat-producing devices such as turbines, steam pipes, etc., conditions may be less favorable. Unfortunately, very few reliable data are available for such cases. There may also be indoor installations, especially in factory buildings with glass roofs, where the heat from sun radiation may raise the indoor temperature above the outdoor. Since these last two conditions may apply to an appreciable percentage of electrical apparatus, the compilation of data for installations of this nature seems desirable. However, the ambient temperature conditions given in this discussion, together with the information in Mr. Penney's paper and the Smith and Tenney paper should be of value in the application of electrical ap-

Phase Occurrence of Arc-Backs in High-Current Mercury-Arc Rectifiers

W. E. PAKALA
ASSOCIATE AIEE

W. B. BATTEN
ASSOCIATE AIEE

THE phenomenon of arc-back in mercury-arc rectifiers is the major factor in determining present-day designs. To keep the frequency of occurrence of arc-back sufficiently low, the anodes are set at a sufficient distance from the cathode, shields, baffles, and grids are interposed, and cooling water temperatures are kept in a rather narrow range. These practically successful means for overcoming arc-backs were developed largely empirically as the cause and nature of arc-back is still little understood.

In the normal operation of rectifiers, a transient small inverse current flows to each anode just after its voltage polarity reverses at the end of each normal current-conducting period. This inverse current is a maximum just after transition from the normal conducting to normal insulating state of the anode, and decreases rapidly to a small fraction of its initial value in less than ten electrical degrees, under usual operating conditions. The inverse current is believed to consist of positive ions reaching the anode from the rapidly disappearing residual ionization left before the anode in the preceding conduction period. Most investigators express a belief in a strong causal relationship between this inverse current and the arc-back frequency. The fact that the means mentioned in the preceding paragraph for reducing arc-back frequency also reduce greatly the inverse current seems strongly to support this view. Prince and Vogdes,[1] however, state that "if there is any connection between arc-back and the inverse current, it is probably rather remote."

Little is known as to where in the alternating cycle arc-back occurs. If the

---

paratus, particularly transformers, the greater number of which are outdoors or in well-ventilated areas.

G. W. Penney: Natural convection depends on low-velocity air movements and therefore varies with the shape and size of the surface, type of ventilation in the room, and similar factors which are not normally closely controlled, so that rather large variations are to be expected between results obtained under various conditions. W. H. McAdams in his book on "Heat Transmission"[5] has compiled a good summary of available data. The curves of figure 1 are believed to represent average conditions for large objects.

As Mr. Montsinger mentions, natural convection for small objects is frequently assumed to vary inversely as the one-fourth power of the height, but this simplification usually requires some adjustment of constants. McAdams (page 244) gives a curve showing the variation of convection with height of cylinder which would give convection as varying inversely with a fractional power of the height up to 10 inches and then gradually changing to a constant value for heights over 18 inches. In reply to Mr. Montsinger's question as to the value used for the 100-watt transformer mentioned in the paper, if we use the formula for convection as a function of height as given by McAdams on page 245, equation 32, a value of 12 per cent greater than that given by figure 1 would be obtained. However, the transformer was tested sitting on a wooden platform as shown in figure 6. This platform somewhat obstructed the natural convection so that it was believed that the curves of figure 1 probably came very close to the actual condition.

Heat dissipation due to wind velocity depends on the size of the object and is also commonly approximated as varying inversely as the one-fourth power of the size of the object cooled so that the relative effect of the wind tends to be independent of the size of the object cooled.

Mr. Hellmund asked as to the effect of mounting apparatus in small outdoor enclosures, these enclosures being exposed to the sun. If the enclosure is not ventilated and if its temperature could be assumed to be uniform, the approximate methods suggested in the paper could be used to estimate the effect of the sun. Such a calculation would give an idea of the order of magnitude of the sun effect. However, the temperature throughout the case will not be uniform, and the sources of heat will be irregularly located so that tests should be made if exact figures are needed. A number of tests under typical operating conditions would be desirable.

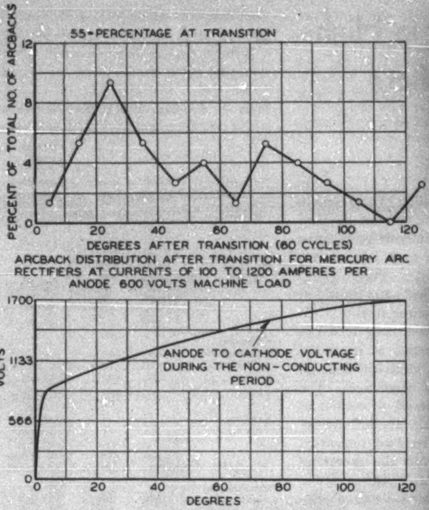

Figure 1 (above). Arc-back distribution and inverse voltage of a mercury-arc rectifier

Figure 2a. Oscillogram of an arc-back which occurred at transition

Figure 2b. Oscillogram of an arc-back which occurred 86 degrees after transition

inverse current is the controlling cause, then all arc-backs should occur immediately after transition, since under normal operating conditions for low-voltage rectifiers, there is considerable inverse current only just after transition. Actually the belief is quite widespread that arc-backs occur almost entirely at transition. Prince and Vogdes,[2] however, give a contrary viewpoint, and describe experiments with a tube in which quite definitely the arc-backs did not take place at transition. However, the tube used in their experiments was very special, so that it might still be believed that in practical low-voltage rectifiers, arc-backs occur only at transition.

It is difficult to determine the time of occurrence of arc-backs by usual oscillographic means with rectifiers operating under normal conditions, because of their completely random and infrequent occurrences. However, the development of the "memnoscope"[3] has solved these difficulties so that there has now accumulated a considerable number of oscillographic records which permit a direct determination of the time of occurrence of arc-backs in practically operating rectifiers. These records indicate that arc-backs occur frequently throughout the whole inverse period.

Table II. Per Cent of Arc-Backs at Transition for Each Rectifier Unit

Rectifier Tested	Number of Arc-Backs Observed	Per Cent at Transition
Six-phase ignitron, 300 volts	10	90
Six-phase multianode tank rectifier, 600 volts	3	67
Six-phase ignitron, 600 volts	5	20
Three-phase ignitron, 600 volts	1	0
Six-phase ignitron, 300 volts	6	33
Six-phase ignitron, 600 volts	2	50
Six-phase ignitron, 600 volts	5	80
Six-phase ignitron, 600 volts	22	66
Single-phase full-wave ignitron, 600 volts	20	35

Test Conditions and Procedure

All the oscillograms were taken on the test floor or in the laboratory, on commercial 300- and 600-volt rectifiers feeding a d-c motor. Currents ranged from 100 to 1,250 amperes per anode with zero ignition angle.

Anode to cathode voltages of all the anodes of a rectifier under observation were brought to memnoscopes whose outputs were passed through the elements of a magnetic oscillograph with continuously rotating cylindrical film. On occurrence of an arc-back, a reverse-current relay opened the oscillograph shutter, and a photographic record was thus obtained of the anode to cathode voltages preceding, during and after the arc-back. From these oscillographs the time of occurrence of the arc-back could be determined.

Results

Seventy-four oscillograms were obtained with arc-back occurrence times, as shown in table I. Two typical oscillograms are shown in figures 2*a* and 2*b*.

Forty arc-backs or 54 per cent occurred at transition. The remaining 34 or 46 per cent were distributed through the inverse period.

The curve of figure 1 shows the distribution of these 34 arc-backs through the inverse period. Only one was observed at more than 130 degrees after transition. It occurred at 170 degrees and another anode arced back a few degrees later.

By direct experiment with a deck of cards it was found that the curve of figure 1 is not inconsistent with the hypothesis that the probability of arc-back is the same in each of the 10-degree intervals making up the 130 degrees. That is, 34 points placed at random in the 13 10-degree intervals gave distributions with as great a saw-tooth irregularity as shown in figure 1.

Discussion

The fact that only one arc-back was observed at more than 130 degrees later than transition may have been not because the later ones have a lower probability of occurrence, but rather to the method used for tripping the oscillograph shutter. On the six-phase rectifiers the oscillograph shutter was tripped by the reverse-current breaker, hence no record of arc-backs which clear without fault, if there are such arc-backs, was obtained.

There are not a sufficient number of arc-backs to obtain the true form of the distribution curve. About all that can be said definitely from the results obtained is that not all arc-backs have a probability of occurrence which is a strongly varying function of the instantaneous positive ion current density. The most that can be said in this direction would be that there are several types of arc-backs; and that one type, which constituted 54 per cent of the total, is occasioned by the momentary positive-ion current.

On the other hand, other possibilities will fit the above results. For example, we may postulate that arc-back causes occur at random throughout the cycle, but with effects lasting a cycle or more. In this case all causes which occur during the conducting period will produce their effect at transition and their number will depend on ratio of conducting to nonconducting period in the rectifier. If there is an equal probability for the whole inverse period, then for the double three-phase rectifier connection we should obtain 230°/360° = 63.8 per cent of the arc-backs after transition and 36.2 per cent at transition. However, as can be seen from table II for the nine rectifiers tested, the fraction for each rectifier occurring at transition is very variable, which makes the possibility just discussed rather unlikely.

Station-Type Lightning-Arrester Performance Characteristics

AIEE LIGHTNING-ARRESTER SUBCOMMITTEE

THIS PAPER presents the results of additional work by the AIEE lightning arrester subcommittee and contains station-type-arrester performance values which may be expected of present-day commercial station-type arresters rated from 3 to 245 kv. The characteristics of line-type arresters were presented by the subcommittee in the May 1937 and November 1938 issues of Electrical Engineering.

Table I includes station-arrester impulse gap breakdown values obtained from tests using the rate of voltage rise specified in the AIEE Standards for lightning arresters No. 28 or ASA Standards *C-62*; that is 100 kv per microsecond per 11.5 kv of arrester rating. To enable a more complete analysis of arrester performance, a complete curve (figure 1) of arrester gap breakdown voltage is included as a supplement to the tabulated values. This curve is plotted in per cent of the arrester's maximum permissible line-to-ground voltage rating, using the crest value of the voltage rating as the 100 per cent of reference point. The actual breakdown voltage for any arrester at any time *T* can be obtained by multiplying the crest value of the arrester's maximum permissible line to ground voltage rating by the percentage value indicated for any time *T* on the curve.

The 60-cycle spark potential of the arresters referred to in this report will not be less than 150 per cent of the arrester's maximum permissible line-to-ground voltage rating.

The table of arrester-performance values also includes the *IR* discharge voltage of the arrester valve element for currents of 1,500, 3,000, 5,000, 10,000, and 20,000 amperes, all of which are based on a current wave having a time to crest value of 10 microseconds and a time to 50 per cent of the crest value on the tail of the wave of 20 microseconds.

The lightning-arrester manufacturers have furnished the data from which the average characteristics of available station arresters are plotted and tabu-

lated. These values hold for new arresters and do not necessarily hold for the older types of arresters.

Tolerances are given to include the expected variation from the average values referred to above. The tolerance from the average value of gap breakdown is ±20 per cent and the tolerance from the average value of the *IR* discharge voltages is ±15 per cent.

By comparing the complete volt-time curve of the arrester with the complete volt-time characteristic of the insulation to be protected, a reasonable evaluation can be made of the margin of protection obtained.

The Measurement of Spot-Welding Current

WENDELL F. HESS

ALBERT MULLER
NONMEMBER AIEE

CURRENT is an essential factor in the complete specification of spot-welding conditions. Therefore, the need for the measurement of spot-welding currents arises, if optimum conditions determined in experimental laboratories are to be duplicated in production shops. Laboratory methods must be accurate and supplemented by facilities for ready calibration into secondary amperes. Shop methods must be convenient, reasonably accurate, and free from the possibility of accidental error. Shops find current measurement of great value in resetting welding machines for conditions which have previously been found satisfactory.

The problem is complicated by several factors, chief of which is the duration of current flow, which is commonly of the order of one-tenth second, but may be more or less. Another factor is the variable transient current produced by nonsynchronous closure of the welding circuit. A third factor is the wave shape of the welding current. Methods which depend upon the peak value of the current, or the rate of change of the current as it passes through its zero value, will be satisfactory for sinusoidal current waves. However, such methods will be of no value with wave shapes such as are produced by phase control of the firing of mercury-vapor tubes, or the wave shapes of stored-energy discharges.

The present paper includes brief descriptions of a variety of methods of current measurement, together with our evaluation of the methods, based upon experience in using them in spot-welding research programs, and upon the work of Mr. Muller in the preparation of his master's thesis. More recently a number of tests involving simultaneous determination by different methods have been made for the comparisons presented in this paper. The necessary calibrations to convert readings to secondary amperes were also performed. The magnetizing currents for the welding machine were determined through the range of the comparison tests to establish corrections for primary current readings.

Methods of Current Measurement

Figure 1 diagrammatically illustrates various methods of measuring spot-welding current. The solid lines connecting the instruments to the welding circuit indicate the connection which we prefer to use. The dotted lines indicate alternate methods of connection. We shall discuss these methods individually in the following order:

1. Electromagnetic oscillograph with secondary shunt
2. Electromagnetic oscillograph with primary shunt
3. Current-crest meter
4. Cathode-ray oscillograph with primary shunt
5. Pointer-stop ammeter with primary clamp-on current transformer
6. Vacuum-tube voltmeter with secondary current transformer
7. Neon-tube meter with secondary toroid

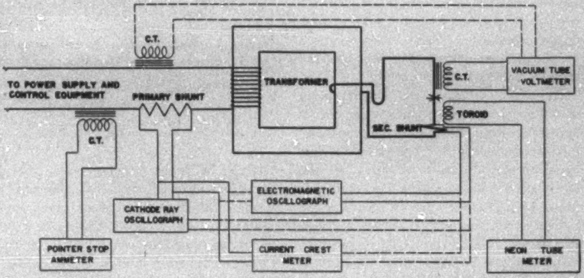

Figure 1. Various methods of measuring spot-welding currents

Electromagnetic Oscillograph—Secondary Shunt

The shunt used with this method is a hollow cylinder of manganin, built into one of the water-cooled electrode holders. The first shunt built for this purpose was silver soldered into the copper electrode holder but this method was found to have softened the copper to an objectionable degree, so that later a double male-threaded construction was adopted. Potential connections to the shunt are of the knife-edge type usually employed for the precise determination of low resistances in the Kelvin double bridge Figure 2 shows a photograph of the arrangement of connections and location of the secondary shunt in the electrode holder. The resistivity of the manganin was determined with the material in the form of a hollow cylinder, about six inches long, in a Kelvin double bridge. The cylinder had an external diameter of one and one-quarter inches and an internal diameter of one-half inch. Calculation shows that the skin effect of this bar is negligible. A twisted pair of conductors carry the potential connections away from the shunt in a direction perpendicular to the electrodes and parallel to the plane of the secondary loop. Care must be taken to avoid the introduction of vertical loops in the circuit, by properly backtracking and arranging the leads at the point where the conductors leave the shunt. The effectiveness of these precautions to eliminate induced voltages from the potential circuit should be checked experimentally. This may be accomplished by taking an oscillogram during the passage of welding current, with the oscillograph connected to the potential circuit which is short-circuited and insulated from the shunt.

The simplicity, directness, and precision of the calibration involved in the use of a secondary shunt make this method a

standard of comparison for other methods. If current were the only measurement desired, a simpler method than the use of the secondary shunt could be used. Our greatest use of the method has been in the determination of resistance and energy values in spot-welding circuits. This involves simultaneous determination of voltage drops in the parts of the circuit being investigated, and current measurement with the shunt. An example of this type of measurement is shown in the oscillograms of figure 3. The fact that these voltages and current are in phase indicates that inductive pickup has been eliminated, and that the quantities measured are purely resistive in character.

Electromagnetic Oscillograph—Primary Shunt

This method is simpler than the one previously discussed. A shunt for use in the primary circuit is a standard piece of apparatus, which is therefore easy to purchase. It may even be constructed without much difficulty and is simple to calibrate and install. The use of a primary shunt does not involve as much precaution as does the secondary shunt, to avoid the pickup of induced voltages.

In common with all methods involving measurement of primary current, it is necessary to make measurements of transformer ratio for all winding arrangements which are used. The transformer ratios are obtained by dividing the primary voltage by open-circuit secondary voltages. It is also necessary to correct the total primary current for its magnetizing component before calculating the secondary current. It is common practice to measure the magnetizing current under open-circuit conditions, and in the case of a welding machine, to subtract this from the total primary current arithmetically rather than vectorially. This procedure is not much in error since the power factor of the welding machine is usually so low that the magnetizing and load components of the primary current are nearly in phase. In many cases the magnetizing currents will be so small that they can be neglected, but this should never be done unless tests have shown this to be true. If transformers are overexcited or improperly designed, the magnetizing currents may be large.

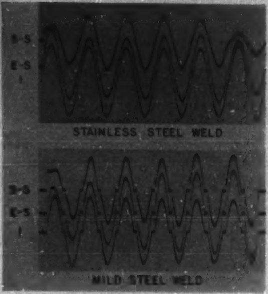

Figure 3. Oscillograms of voltage drops in secondary of spot-welding circuit

I—Voltage drop across shunt

Current-Crest Meter

This method of measurement uses an electromagnetic-oscillograph element to measure the drop in potential across a shunt in the welding circuit, usually on the primary side of the welding transformer. The oscillograph element deflects a light beam upon a translucent scale, usually graduated in millimeter divisions. No attempt is made to sweep the light beam across the screen and introduce a time axis. The reading of the meter consists in observing the amplitude of the deflection of the spot of light during the passage of the welding current. This reads the peak value of the current. If the wave form of the latter is sinusoidal, the effective value of the current may be calculated by well-known relations. With a little practice an observer may easily read these deflections to a half millimeter, and thus determine the welding current with an error of not over two per cent. These readings are most easily taken when synchronous closure of the circuit avoids the introduction of transients. If transients do occur, their magnitude may be observed. Readings may be taken by this method even if the time of current flow is only one or two cycles. The pointer has such low inertia that there is no problem with rapid response such as provides difficulty with an ordinary ammeter or even with the pointer-stop ammeter.

The writers are not acquainted with a meter which is actually manufactured and sold for this purpose. One of the elements of an ordinary portable, two-element oscillograph has been used by us for this type of measurement. Such a meter would appear to be a very useful laboratory instrument.

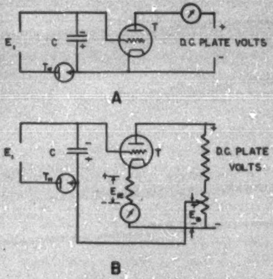

Figure 4. Fundamental vacuum-tube voltmeter circuit

Cathode-Ray Oscillograph—Primary Shunt

A limited amount of experience indicates that a cathode-ray oscillograph may be satisfactorily used in the same way as the current-crest meter above described. The calibration of this meter will not remain permanent so that a means for adjusting the amplifier gain to bring the meter into calibration must be available. A simple circuit, using a voltmeter, variable alternating voltage, and voltage divider, may be set up permanently to accomplish the above calibration easily and as frequently as desired.

A cathode-ray oscillograph is frequently available in a welding laboratory for checking wave forms, transient conditions, and phase-control settings, so that the possibility of using this instrument for current measurement may prove desirable.

A word of caution regarding the use of the cathode-ray oscillograph for current measurement is necessary because of the fact that these instruments are frequently affected by the magnetic field of the welding currents. This difficulty may usually be overcome by placing the instrument at a reasonable distance from the welding machine and by turning the instrument in such a direction as to minimize disturbance. The instrument must be calibrated in the exact position used for current measurement.

POINTER-STOP AMMETER

This instrument is commercially available together with calibrated leads and a clamp-on current transformer for use on the primary circuit. The ammeter consists of an ordinary instrument to which is added an adjustable stop which may be moved up behind the pointer. In measuring the short-duration spot-welding current, the pointer is gradually moved up the scale by adjusting the stop until the pointer just leaves the stop when a weld is made. Thus the current does not have to move the pointer all the way up the scale, but only a sufficient distance to indicate that the current is very slightly greater than the value set by the stop. To determine a value of current, it is necessary to make several welds in order to approach the correct setting of the stop for that value of welding current.

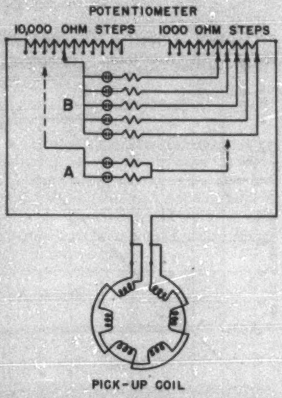

Figure 5. Fundamental neon-tube meter circuit

This instrument possesses a great advantage in simplicity of reading and ease of attachment to the circuit. It is very suitable for setting a welding machine to a particular value of current. It is necessary only to set the pointer, by means of the adjustable stop, to the value desired and then to adjust the current control until the making of a weld causes the pointer to slightly leave the stop. A further advantage of this method is that it may be used to determine the effective value of phase-controlled currents, which of course are not sinusoidal.

Among the disadvantages of this type of meter are the errors resulting with nonsynchronous circuit closure due to the transients produced, and the optimistic readings resulting from the double-frequency deflecting torque. The deflecting torque periodically varies above and below the control torque. When the pointer is moved up to the value of current which should be indicated, the tendency of the control torque to reduce the deflection below the average value is prevented by the pointer stop. Under these conditions the pulses of the deflecting torque above the average value tend to cause the pointer to jump away from the stop. A false indication of a higher value of current is thus given. In consequence of this we have commonly found a pointer-stop ammeter to consistently read five to eight per cent high. Less significant disadvantages consist of those common to all methods of measuring primary current, and which have already been discussed under the section describing the use of the electromagnetic oscillograph with a primary shunt. We have found also that the pointer-stop ammeter reading falls off when the time of current flow is three cycles or less. The amount of this falling off is not serious for a welding time of three cycles and amounts to only four per cent in two cycles.

VACUUM-TUBE VOLTMETER

Our experience with this type of instrument for the measurement of current has been made possible by the generosity of two men[1,2] who have been responsible for original development work. Each has kindly loaned us his instrument for study. Figure 4 shows the fundamental circuits in which the vacuum-tube voltmeter is used to measure the welding current in terms of the drop in potential across a shunt connected in series with the secondary circuit of a current transformer. The current transformer which we have used is designed for use in the secondary circuit by slipping the transformer over the electrode holder. The basic principle involved in this method is illustrated in figure 4*A*. The voltage drop, E_1, across the shunt on the current transformer charges the capacitor *C* through a rectifying tube T_R. This causes the grid of the measuring tube to become more negative, thus reducing the plate current. The capacitor is expected to retain its charge and thus maintain the reduced plate current for a sufficient time to permit reading. Figure 4*B* illustrates a second stage in the development of the circuit of this meter. Two desirable features of adjustability are provided in this circuit. The sliding contact with the indicated voltage drop, E_B, permits adjustment of the plate current to the de-

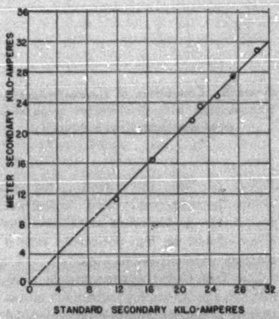

Figure 7. Comparison of primary-shunt measurements with simultaneous secondary-shunt measurements as a standard using an electromagnetic oscillograph in both cases

---

[1] For all numbered references, see list at end of paper.

sired top-scale value, before each reading. The resistance associated with the voltage drop E_B in the cathode lead permits adjustment of the over-all sensitivity of the circuit.

One of the principal advantages of this instrument is that the readings are definite and may be obtained with one weld. Also, the secondary current may be measured directly. With circuit refinement to delay the charging of the capacitor the meter may be used to measure welding currents with large transients existing during the first few cycles. Such transients are caused by nonsynchronous closure of the welding circuit, and render inaccurate the measurement of current by almost all methods except the oscillographic.

The difficulties with the vacuum-tube voltmeter are associated with the current transformer and with the fact that it is a peak-reading instrument. The design of an iron-core current transformer to handle such heavy currents involves some sacrifice in portability. The introduction of so much iron into the secondary current loop affects somewhat the output of the welding machine. In our case with a short-throat machine, the output is reduced about three per cent when the current transformer is placed in position. This effect should be less noticeable with a machine of larger throat area.

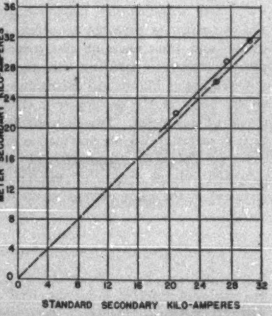

Figure 8. Comparison of current-crest-meter measurements with simultaneous secondary-shunt measurements as a standard

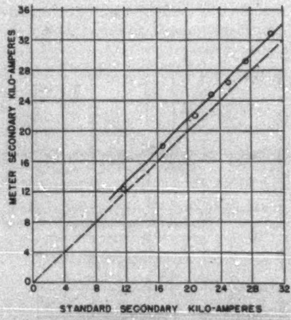

Figure 9. Comparison of pointer-stop-ammeter measurements with simultaneous secondary-shunt measurements as a standard

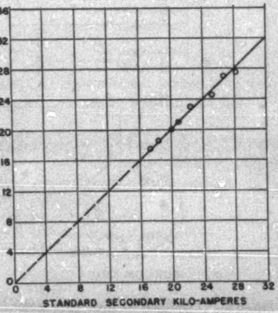

Figure 10. Comparison of vacuum-tube voltmeter measurements with simultaneous secondary-shunt measurements as a standard

The fact that the vacuum-tube voltmeter is a peak-reading instrument means that it is not suitable for nonsinusoidal currents such as are caused by the phase control of mercury-vapor tubes. A suggested method of dealing with these currents is impractical to use since it involves the use of full heat, which probably cannot be absorbed by the work.

NEON-TUBE METER

A meter that employs neon-glow lamps as voltage indicators in conjunction with a potentiometer and pickup coil was also investigated. The circuit of this meter is shown in figure 5. An air-core pick-up coil of the toroidal form is used in the secondary circuit of the welding transformer. The voltage induced in this coil is applied across a potentiometer. The original and basic voltage indicating circuit[8] employs two neon-glow lamps connected in parallel across the same points on the potentiometer as shown at figure *5A*. Lamps having nearly the same critical voltages are selected for this purpose. As welds are made, the potentiometer connections are progressively changed until a point is reached at which just one of the lamps glows. The magnitude of the secondary current is then obtained directly by reference to the meter calibration.

In the present investigation it was desired to determine the approximate potentiometer setting more quickly and with fewer welds. Therefore a bank of five matched neon-glow lamps is employed as shown at figure *5B*. By means of switches the entire range of the potentiometer can be explored in four steps. At each step the number of lamps that glow when a weld is made is observed and the approximate setting is that above which all lamps glow. Frequently, however, only one or two welds are necessary to obtain an approximate setting. A high resistance is connected in series with each lamp to avoid the shunting effect of those lamps that pass current. After the approximate setting is determined in this way the final meter reading is determined by means of the basic two-lamp circuit which has already been discussed.

A typical calibration of this meter is shown in figure *6A*. This calibration was obtained by using the electromagnetic oscillograph and secondary shunt as the standard means of current measurement. The voltage induced in the toroid is a direct measure of the secondary current, if it is sinusoidal. A voltage-current characteristic of the toroid used in this investigation is shown in figure *6B*. In order to control the voltage applied to the potentiometer, provision is made for connecting the pickup coils in series for measuring low currents and in parallel for high currents. This is very important because, as shown in figure *6C*, the change in critical resistance for a given change in applied voltage becomes much greater as the applied voltage approaches the critical voltage of the lamps.

This type of meter is probably most useful in its basic form. Its primary advantage is its simplicity and low cost. When used simply as an indicator it does not necessarily have to be calibrated. For example, after the optimum welding conditions have been established for a given job, the reading of the meter can be recorded and then used in checking when the job is set up again at a later date. In our experience this meter was only used in measuring synchronously-timed currents. Its use with nonsynchronous timing should not be attempted since the maximum rate of change of welding current, which the meter actually measures, is only simply related to effective value for sinusoidal currents. Calibration and use of the meter requires that the critical voltage of the lamps remain constant with time, a relationship about which more information is needed. In general, experience thus far indicates that further development of this type of meter might prove to be worth while.

Comparison

Figures 7, 8, 9, and 10 are plotted for comparison of results by different methods. These are plotted using simultaneous secondary shunt measurements with an electromagnetic oscillograph, as a standard of comparison. The dotted curves would represent exact agreement. The solid lines represent the instrument readings. The primary shunt and vacuum-tube voltmeters give excellent agreement. The current-crest meter seems to have an optimistic tendency although the readings are within the limits of experimental error to be expected with this method—that is, about five per cent. The decidedly optimistic tendency of the pointer-stop ammeter is evident in figure 9.

It is hoped that this experience may prove helpful to those who have the problem of measuring such currents, and that it may be an encouragement to others to continue the development of these and possibly better methods of spot-welding-current measurement.

Discussion

C. Stansbury (Cutler-Hammer, Inc., Milwaukee, Wis.): For several years we have been using the neon-tube type of meter. In our design the two neon tubes, calibrated rheostat, and switch for selecting the range are mounted directly on one side of the case in which the air-core toroid is built. Recent models are arranged so that the toroid can be opened up by means of a hinged construction for convenience in placing it around the welding electrodes or primary conductors. Also in recent models only one neon tube is employed. It has been found that these small neon tubes have a slightly different starting voltage for the two halves of the a-c wave and about the same result in bracketing the reading can be obtained with one tube as with two, with less chance for confusion.

With regard to using this meter on nonsynchronous circuits, although no great precision is obtainable, results sufficiently accurate for most practical purposes can be obtained by making a number of welds and using the highest setting which causes a glow on all of the welds. Welds on which the circuit happens to be closed so as to cause minimum transients correspond to the lowest setting of the instrument for which a glow is obtained. We use the meter in either the primary or secondary circuit as most convenient.

As we are not manufacturing this meter commercially, we have not been able to follow up certain things about which we would like to have more information as a matter of general interest.

Some time ago I had occasion to use the meter in the secondary circuit of a spot welder in which the primary current was controlled by ignitron tubes. These ignitron tubes were not synchronously controlled, but were controlled by a relay timer which caused random completion of the circuit. Under these conditions, the meter could not be used at all in the secondary circuit since the tubes glowed at all positions of the dial. When the meter was connected in the primary circuit, it worked satisfactorily. In using the meter in the primary circuit we ordinarily use a flexible, heavy connector and make several passes through the toroid.

Although I did not have an opportunity to determine the reason for this with an electromagnetic oscillograph as I wished, I did try to do so with a cathode-ray oscillograph. This instrument was so seriously affected by the magnetic field around the welder that I could not get any satisfactory results. As the authors state, the cathode-ray oscillograph is very unsatisfactory around a resistance welder for this reason.

A point which I would like to see brought out clearly, either in an appendix to this paper or elsewhere, is the difference in characteristics between an air-core toroid operating with negligible back ampere-turns and the conventional iron-core current transformer.

G. F. Gardner (nonmember; General Electric Company, Schenectady, N. Y.): By drawing attention to the necessity for accurate current measurements in welding, the authors have performed a great service to all who are in any way interested in spot welding. The measurements have evidently been carried out with great care and each method has been given the consideration which it deserves.

In connection with the electromagnetic oscillograph-secondary shunt method, the authors do not state the highest values of current which have been measured in their tests, but it may be of interest to note that measurements have been made on welding machines using similar shunts at currents up to 80,000 secondary amperes.

The electromagnetic oscillograph-primary shunt method is also of definite value. It would seem, however, that if it were to be generally applied, the use of a current transformer might be somewhat preferable to the shunt from the standpoint of ease of application and safety to the operator. Care should, of course, be taken to select a transformer whose limitations are not exceeded.

Current-Crest Meter. In considering this and the methods which follow, attention should probably be directed to the quantity which it is desired to measure—either the root-mean-square or the peak value of the current. Granted that it is possible to measure some transients and take account of their influence using this type of instrument, it nevertheless must be borne in mind that its indications are as dependent as any other of the crest measuring instruments upon the peak value of the wave. It was noted with considerable interest that the authors mentioned that such an instrument would be a useful laboratory tool. Experimental samples of such devices have been constructed and it is hoped that one will appear on the market shortly.

Cathode-Ray Oscillograph—Primary Shunt. The word of caution regarding the use of this instrument is certainly not out of place. Some of our experience indicates that a reasonable distance for an unshielded instrument may be as much as 40 feet from the welding machine.

Pointer-Stop Ammeter. It was gratifying to note the authors' experiences with this relatively simple type of instrument since at this stage of the welding measurements art, it appears that the choice is often between a simple means of current measurement or none at all. As regard the "optimistic" indications, this is not an essential feature of the pointer-stop ammeter and instruments can be so designed that they show but very little, if any, increase in reading due to the conditions mentioned by the authors.

The closing paragraph of the authors' work is especially significant and, in line with this, it may be of interest to mention further work which has been done along this line. A device has been made available known as the weld recorder which will give an accurate indication and record of the ampere-squared-seconds existing for a given weld. If the ampere-squared-seconds are not within preset limits, such as plus or minus five per cent, a bell rings and the machine is automatically locked out. The record will show whether the I^2t is above or below the limits. Nearly 100 of these have been made and have been found to have been very useful in establishing levels for resistance-welding measurements and, although their use has been restricted to comparative work at the present time, there is no reason why they could not be applied where definite values of ampere-squared-seconds are required. Space does not permit a full description of the instrument characteristics here, but it is hoped that it will be possible to publish an article containing this at an early date.

A. J. Corson and **E. W. Clark** (nonmember; both of General Electric Company, Lynn, Mass.): This paper is a very thorough and balanced evaluation of several existing methods of measuring spot-welding currents. It is hoped that it will stimulate interest, not only in the improvement of these methods, but in the application of them as well. The following discussion is based on a somewhat similar series of experiments, during which a comparison of the secondary shunt and oscillograph was made with the pointer-stop ammeter and the vacuum-tube voltmeter.

Figure 7 shows excellent agreement between the primary- and secondary-shunt readings. The primary-shunt readings were presumably multiplied by the welding-transformer ratio as determined by the voltage method. This indicates an absence of errors due to such causes as saturation of the welding transformer, and varying current distribution in the secondary shunt, for the particular conditions of this test. It is doubtful if these conditions would apply to all welding transformers and all secondary loops. For these reasons, we prefer the use of the current method in determining this transformer ratio using a specially designed current transformer in the welder-transformer secondary since it more nearly simulates operating conditions and also avoids the necessity of measuring very low alternating voltages. Also in the interest of minimizing current distribution errors in the secondary shunt, this device was reduced to a minimum axial length 0.080 inch, as compared to the six-inch dimension described in the paper.

The response characteristic of the pointer-stop ammeter is, as indicated by the authors, somewhat dependent on the duration of the impulse. It would be of interest to know, therefore, what duration was used in determining the curve given in figure 9, also what interval of travel was allowed for the pointer oscillation. It would appear that this characteristic, while definite for an instrument of given design constants, is not universal, and by modification of these constants, improvement could be obtained in accuracy. In the meantime the application of a simple correction curve will result in a highly satisfactory degree of accuracy for all ordinary work.

W. F. Hess, R. A. Wyant, and A. Muller: In answer to the implied question in the second paragraph of Mr. Gardner's discussion, the maximum secondary root-mean-square amperes which we have had occasion to measure with the oscillograph and secondary shunt is 40,000 amperes.

Mr. Gardner makes a good point in his third paragraph with regard to the safety of the operator when using a shunt in the primary circuit. Care should be taken to mount the shunt so that there will be no occasion to come in contact with it while the primary circuit is energized, and to bring out insulated potential connections. The substitution of a current transformer for the primary shunt in oscillographic work is open to some objections. The wave forms may be distorted by transient currents produced in the secondary of the current transformer. These may be reduced by careful adjustment of the phase angle of this circuit to coincide with the angle of firing of the main power tubes. This adjustment would be an objectionable added complication. The calibrations involved are more complicated. The selection of a shunt to be used with the current transformer and oscillograph must be carefully made to secure good sensitivity and at the same time to avoid overloading the current transformer. Great care must be taken to insure continuity of the secondary circuit of the current transformer to avoid the hazardous voltages which are produced by an open-circuited current transformer. The more precise current transformers are usually not of the clamp-on type. It is therefore almost as difficult to attach them to the welding circuit as to install a shunt. Phase-angle errors are objectionable when simultaneous measurements of voltage drops and current are desired.

Our experience coincides with that of Mr. Stansbury in that the two electrodes of a single neon tube are as effective as two separate tubes in determining the final setting of the voltage divider which measures the toroid voltage.

In response to the suggestion in the last paragraph of Mr. Stansbury's discussion we offer the following. When a toroidal coil is placed around a conductor carrying an alternating current, a portion of the magnetic field set up by the current will link with the coil and induce a voltage proportional at any instant to the rate of change of the current. The peak voltage which we measure is therefore a measure of the maximum rate of change of current. Only for sinusoidal currents is the effective or heating value proportional to the maximum rate of change of the instantaneous value. Hence only such currents will be correctly measured by the peak value of the voltage developed in a toroidal coil.

A precaution that must be exercised in the use of a toroid is that the voltage must be measured without drawing appreciable current from the winding, since any current taken will tend to distort the flux set up by the current being measured, displacing it from within the toroid and causing the toroid voltage to drop.

In the case of the iron-core current transformer, a current must be permitted to flow in the secondary winding which balances at every instant the magnetic effect of the primary current. If such a secondary current does not flow, the flux density in the core will tend to rise and the secondary current will no longer be proportional to the primary current. Also the primary winding and iron core will act as a choke coil or reactance in the power line, and will absorb large energy losses from the line which it is incapable of dissipating. On the other hand if the resistance of the secondary circuit is kept sufficiently low, so that the current-transformer core does not saturate, then the current in the secondary will be a direct measure of the primary current even with considerable departure from sinusoidal wave shape.

In reply to the discussion of Messrs. Corson and Clark, the transformer ratios used in calculating secondary current from primary readings were, as stated in the body of our paper, determined by voltage readings. It is true that for the comparison tests presented in the paper the magnetizing currents were so low as to be negligible, indicating the absence of any approach to saturation of the welding transformer. Before using any method involving primary-current readings we have recommended the measurement of magnetizing currents for all settings of the welding transformer. If the magnetizing currents are found to be appreciable, as they may be on the higher taps of the transformer, the primary readings should be corrected for magnetizing current, before applying the transformer ratio to calculate the secondary current.

If the transformer core is approaching saturation, as evidenced by relatively high magnetizing current, there will be an error in determining the transformer ratio by voltage readings, due to primary leakage impedance. The voltage drop due to this impedance should be subtracted from the applied primary voltage to obtain the primary voltage induced by the mutual flux, which latter should be divided by the secondary open-circuit voltage to obtain the true transformer ratio. Owing to the difficulty of measuring the separate primary leakage impedance, another approach to the determination of transformer ratio is preferable. For those welding-machine connections which give rise to appreciable magnetizing current at rated voltage, the primary and secondary voltage readings should be taken with the primary voltage at such a reduced value as will avoid an excessive magnetizing current. The turn ratio may then be calculated from these readings without appreciable error.

The use of primary and secondary current transformers to determine the transformer ratio involves the use of special costly equipment not readily available, and would appear to involve at least as much chance for error in the two transformers and accompanying meters as should be expected with the voltage method. We have found no difficulty in measuring the low alternating voltages, with a good laboratory instrument. The axial length of the shunt used for secondary current measurement was approximately three-quarters inch between potentiel connections. The total length of manganin in the secondary circuit was about one inch. The six-inch dimension mentioned in our paper was the length of the manganin cylinder used in the calibration measurement to determine resistivity.

The duration of current flow for the curve given in figure 9 was six cycles. It had been determined that no definite reduction in reading occurred until impulses of less than four cycles duration were used. The interval of travel allowed for the pointer oscillation was approximately $^1/_{100}$ inch, which was about the minimum definitely perceptible.

Vector-Response Indicator

B. D. LOUGHLIN
ENROLLED STUDENT AIEE

THE performance characteristics of a communication circuit are often conveniently described in the form of a response curve which indicates the steady-state transmission of the circuit at frequencies within the range of interest. These curves can be obtained by making a sufficient number of individual measurements of transmission at various frequencies within the band of interest and plotting the results; however, considerable time may be saved by the use of a device which indicates directly the desired curve. Many such response-curve tracers are found in radio laboratories, with the curve of transmission or amplification as a function of frequency being obtained as a trace on a cathode-ray tube. However, strictly speaking, the transmission of a circuit, being the ratio of output voltage to input voltage of the same frequency, is a vector quantity having an angle as well as a magnitude—the angle being the phase angle between the output voltage and the input voltage. The response-curve tracers now in general use indicate only the magnitude of the amplification as a function of frequency. The vector-response indicator described in this paper is a unique apparatus that indicates directly both the magnitude and phase angle of the transmission as a function of frequency. This vector response of the circuit is indicated by a special type of pattern on the screen of a simple cathode-ray tube.

Figure 1. Comparison between elliptical-trace and reference-point methods of phase-angle measurement

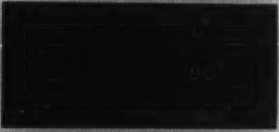

Figure 2. Reference-point method used for a direct-reading high-frequency phase-meter

Some of the new communication systems recently developed have brought about an appreciation of the importance of phase characteristics. For accurate reproduction of a complex voltage wave the circuit must have, over the range of frequencies present in the wave, the properties that the magnitude of the transmission is constant and the phase angle is a linear function of frequency with the intercept at zero or $n\pi$. Except with circuits of long time delay, such as long telephone lines, little or no thought need be given to the phase characteristic requirement in sound circuits, since the ear is not sensitive to moderate phase displacements. However, in television and facsimile systems the complex wave shape must be preserved for acceptable reproduction, and this means that the desirable characteristics must be preserved in both magnitude and phase.

Phase-angle measurements above audio frequencies can be made from the elliptical trace produced on a cathode-ray tube screen when the two sine-wave voltages to be compared are impressed on the horizontal and vertical deflecting plates respectively. The phase angle can be calculated from measurements of the geometry of such a trace. If the phase angle were to vary periodically, as might be caused by a periodic variation of frequency, a series of elliptical traces would be produced, but this trace on the cathode-ray-tube screen would not indicate in a direct manner the variation of phase angle as a function of frequency.

For the vector-response indicator, it was necessary to develop a new method for measuring phase angles, which would give a more direct indication of the angle. This new method differs from the elliptical trace method in that one of the two voltages to be compared is applied to the vertical deflecting plates, the other voltage being used to give a reference pulse which is applied to the control grid of the cathode-ray tube. The reference pulse is obtained from some particular point in the cycle, such as the positive peak; this reference pulse is applied to the grid with such polarity that it causes the beam to become brighter. With a linear saw-tooth sweep applied to the horizontal deflecting plates, the sine-wave trace of the voltage on the vertical plates is seen, together with a bright spot at the instant that the other voltage reaches its positive peak (or other reference point). Thus, the location of the spot along the trace is a direct indication of the phase angle between the two voltages. Figure 1 shows a comparison between the ordinary elliptical trace and the reference-point methods for several phase angles.

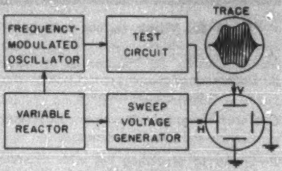

Figure 3. Simplified block diagram of a response-curve indicator

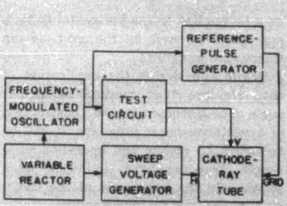

Figure 4. Simplified block diagram of a vector-response indicator

If no sweep voltage is applied to the horizontal deflecting plates, the trace will be merely a vertical line with a bright spot on it; the location of the bright spot indicates the phase angle between the voltages. An appropriate scale might be placed alongside this line and the phase angle read off directly. This is one way of using the reference point method to make a direct-reading high-frequency phase meter. However, to make the exact location of the spot along the line more evident, the pulse voltage

may be applied to the horizontal deflecting plates as well as the grid, giving traces such as figure 2.

Before considering the application of the reference-point method of phase-angle measurements to the construction of a vector-response indicator, it will be well first to review the operation of a simple response-curve indicator that shows only the magnitude of the transmission and not the phase angle.

If a constant sine-wave voltage is applied to the input of a circuit under test, the amplitude of the output voltage, with respect to the input voltage, indicates the transmission of the circuit at that frequency. If further, the frequency of the input voltage is slowly varied, but its amplitude always kept constant, then the variation of amplitude of the output voltage indicates, in some manner, the variation of transmission of the circuit with frequency (that is, the response curve). By varying the frequency periodically, and applying the output voltage to the vertical deflecting plates of a cathode-ray tube, a vertical trace, whose length varies periodically, will be produced. Then by applying a sweep voltage of the same period as the frequency variation to the horizontal deflecting plates, the variation of the length of the trace will be visible. The result will be a trace, symmetrical about a horizontal axis, whose envelope indicates the response curve of the circuit over the range of applied frequencies. Figure 3 shows a simplified block diagram for such a response-curve indicator.

The simple response indicator just described can be easily made into a vector-response indicator by a circuit addition. By adding a circuit which derives a pulse at some reference point in the cycle of the voltage applied to the input of the circuit, and then applying this pulse to the grid of the cathode-ray tube, an indication of the phase angle is obtained (figures 4 and 5). The trace produced now has a bright line appearing within the envelope of the trace. At any abscissa, the relation between the ordinate of this bright line and the ordinate of the envelope indicates the phase angle of the circuit at the frequency corresponding to the particular abscissa. If the reference pulse is obtained at the positive peak of the input cycle, then when the bright line coincides with the top envelope, the output voltage is in phase with the input. When it coincides with the lower envelope, they are 180 degrees out of phase. It may be desirable at times to have a 90-degree leading phase angle indicated by coincidence with one envelope and a 90-degree lag by coincidence with the other envelope. This can be accomplished by producing a 90-degree phase shift between the voltage applied to the test circuit and that applied to the reference pulse generator.

Figure 6. Vector-response patterns for a band-pass amplifier with a double-tuned input circuit and a single-tuned output

A—Proper adjustment of all circuits

C—Insufficient loading in double-tuned circuit

D—Similar to *C* with single-tuned circuit tuned below mid-band frequency

E—Less than critical coupling in double-tuned circuit

F—Similar to *E* with single-tuned circuit tuned above mid-band frequency

A simplified block diagram of the vector-response indicator is shown in figure 4. The variable reactor can be a motor-driven variable capacitor, or a reactance tube, that is, a vacuum-tube circuit arranged to appear like a reactance. The sweep oscillator is synchronized with the variable reactor so that they have the same period. A simple reference-pulse generator might be a vacuum-tube biased beyond cutoff to such an extent that plate current flows only at the positive peak of the applied alternating voltage.

Some illustrations of traces obtained on a vector-response indicator using simple circuits are shown in figure 5. It will be noted that in figure 5*C* there are two zero power factor frequencies, while in figure 5*D* the circuit has capacitive reactance at all frequencies. Figure 6 shows results using a band-pass amplifier with one double-tuned coupling circuit and one single-tuned circuit operating at 175 kc.

All the oscillograms were photographed directly from a small cathode-ray tube (type 902) having a screen of two inches diameter. The apparatus constructed for these tests differed from the simplified block diagram of figure 4 by the use of a beat-frequency signal generator instead of a simple oscillator to generate the desired signals. amplifiers were added where necessary. Figure 7 shows the circuit diagram of the apparatus.

Conclusion

An apparatus has been described that is believed to be new and useful. From the ideas presented there can be developed various phase measuring equipment, such as direct-reading high-frequency phase-meters, phase-characteristic indicators, phase-curve tracers, and time-lag-curve tracers, as well as the vector response indicator described. The increasing use of television and frequency modulation systems should make phase-measuring apparatus such as these of increasing importance in circuit investigation and testing.

Causes of Corrosion of Fine Copper Wires Carrying a Potential

H. N. STEPHENS
NONMEMBER AIEE

G. B. GEHRENBECK
NONMEMBER AIEE

COPPER CORROSION is a serious problem in electrical equipment which uses very fine wires carrying a potential, the outstanding examples being various types of coils used in radios and ignition systems. The usual type of corrosion involves the formation of green material on the surface of the wire, which is obviously due to chemical reaction of the copper with materials in contact with it. As this chemical reaction progresses at a given point in the wire, the cross section of unchanged copper gradually diminishes until finally a break occurs, opening the circuit and rendering the coil useless.

Previous Views of Copper Corrosion

In the past, the question of the actual cause or causes of copper corrosion has often been approached by means of inference rather than experiment, and it is, therefore, not surprising that widely varying views have been held by different people. Probably one of the most popular beliefs is that free acids in materials contacting the wires are responsible. This belief has been the basis of specifications of "acid-free" papers and tapes to be used in the construction of coils. In some cases, specifications are given which require that a distilled water extract prepared by some standardized technique must fall within certain limits of pH. More recently it has been recognized that acids are not the only substances which might cause this effect. Assuming that electrolysis is the fundamental cause of corrosion, it would follow that not only acids but also bases and salts would produce the same effect.

Another similar view is based on the idea that the rate of corrosion of copper wires in contact with a given material is proportional to the conductance, or inversely proportional to the insulation resistance of the material in question.

Again, it has been a common observation that copper corrosion is most serious in high humidities, and this fact has given rise to the belief in some quarters that moisture absorption is the primary factor in corrosion.

Corrosion by Adhesive Tapes

The present study was primarily concerned with the causes of corrosion by adhesive tapes used in the fabrication of coils, and although the results have implications of broader significance, we shall first deal briefly with the specific problem which prompted this work.

Adhesive tapes may be considered as a combination of two functional parts, the adhesive and the backing. We may conveniently consider these in order.

At the present time, electrical-tape adhesives are mainly of the rubber-resin type, although in the past, glue has been used. The use of the latter may be disposed of rather summarily, as it is now known that glue hydrolyzes rather rapidly in high humidities at elevated temperatures, with the production of organic acids of sufficient activity to be a major cause of corrosion. The ill-advised attempts to correct the difficulty by using dialyzed glues, which could be made substantially electrolyte-free, resulted in only a transitory improvement; because in use, the glue itself was a source of electrolytes.

Experimental Study of Corrosion

In view of the fact that corrosion by the more satisfactory electrical tapes developed so slowly under any practical operating conditions, it was necessary to develop an accelerated corrosion test. We therefore canvassed the radio industry, and finally standardized on a test similar to the most severe ones in use. The arrangement consists essentially of two parallel bare copper wires at a potential difference of 90 (later increased to 250) volts direct current held under tension against the surface to be tested, under conditions of 90 per cent relative humidity and 120 degrees Fahrenheit. The specimen was placed on the bowed surface of a moulded block with two binding posts at each end and was held in position by two parallel bare copper wires, spaced $^3/_{16}$ inch apart and each held under slight tension by a pair of binding posts. Originally, number 40 wires were used, but later it was found more satisfactory to use number 32 wires and estimate the amount of corrosion microscopically. At 90 volts, the usual duration of the test was four days.

Glues, however highly purified, were found in this test to be highly corrosive. Purification delayed slightly the beginning of corrosion, but did not result in an important improvement.

The rubber-resin type of adhesive, on the other hand, is not a cause of corrosion, provided that reasonable care and common sense is used in its formulation. The usual adhesive made from rubber, rosin, and zinc oxide also yields, during artificial aging which would correspond to at least five years of natural aging in the absence of light, products which contribute nothing toward corrosion. Thus, in spite of the fact that the very term, "acid", to the layman, is the symbol of death and destruction, we find that an adhesive which contains a large percentage of abietic acid is noncorrosive. Abietic acid and similar resin acids are so weak and so difficultly soluble in water that their acid properties may be neglected.

Corrosion by Cellulosic Backings

The elimination of the adhesive as a factor in copper corrosion by pressure-

Linen	4	
Silk	20	4,000
Wool	1,700	1,400
Cellulose acetate	5,000	10,000

sensitive tapes leaves the backing as the remaining possibility. At first it was assumed that impurities in the paper or cloth were responsible, and we therefore tested a wide variety of papers ranging from cheap wrapping papers through purified papers for electrical uses, and finally, the most highly purified alpha-cellulose obtainable, in the form of ash-free filter paper. The extracts of these various papers, prepared according to ASTM standard *D*-202-34*T*, section 45, showed large differences in both pH and electrolytic conductivity, but although the low-grade papers caused very bad corrosion, we were surprised to find that there was no significant difference in this respect between the most highly purified alpha-cellulose and any good saturating paper. The inference was plain that the cellulose itself (in the presence of water) was causing corrosion, but we were at first so reluctant to accept this conclusion that we attempted to purify the cellulose further by exhaustive extraction, in a syphon extractor, with highly purified water. An additional extraction with highly purified ether was performed in some cases. However, all such purified samples behaved similarly, and there was no noticeable improvement over the unextracted samples. A similar study of the effect of purification on cotton fabrics yielded exactly parallel results.

Now, if cellulose itself, in the presence of water is a source of copper corrosion, cellulosic materials other than paper or cotton ought to show the same behavior. We therefore studied samples of linens and viscose rayons, all free from loading or sizing materials, and we found that they caused corrosion at essentially the same rate as cotton or paper. Regenerated cellulose films such as are used as the base for Cellophane behaved in the same manner. Furthermore, we found that exhaustive extraction of any of these materials as in the case of paper, produced no perceptible improvement. Other fabrics made from natural fibers, such as silk and various kinds of wool, were also found to cause corrosion, but wool was very much superior to all other natural fibers in this respect. Again, it was obvious that impurities were not responsible because exhaustive extractions failed to produce any improvement. It is rather surprising that silk is not much better than cellulose in the matter of corrosion whereas wools, which are also protein fibers, are very much better than either silk or cellulose.

Noncorrosive Materials

The elimination of paper and all fabrics made from natural fibers then led us to search for a synthetic material which would be free from corrosive nature. Briefly, it has been found that there are a number of materials which are satisfactory from a chemical viewpoint; for example, cellulose esters and ethers, rubber and some of its derivatives, and a number of synthetic resins from the polymerization of styrene, vinyl derivatives, or methacrylates. Of the above materials, cellulose acetate is the most economical to use and the one with the best mechanical properties; consequently it is the only one which has been exhaustively tested over long periods of time. It has been tested both in the form of transparent sheets and in the form of cloth woven from the fibers, and apparently is completely free from tendency toward copper corrosion. There is every indication that a fine copper wire in contact with cellulose acetate will last as long as one suspended freely in air.

Possible Causes of Corrosion

After having been compelled to recognize the fact that cellulose itself was a source of corrosion, the next step was to inquire into the reason and several possibilities were investigated. One obvious possibility, to which reference has already been made, is that the corrosive nature of a given substance is a function of its absorptive (or adsorptive) capacity for water. Only a cursory examination of the facts, however, is sufficient to show that this is not so. Wool shows a much higher moisture absorption than cotton, yet is far superior with regard to freedom from corrosive nature. Also, cellulose acetate shows a moisture absorption which is reported to be over half as great as for cellulose itself, yet it is completely free from corrosive nature.

If corrosion is fundamentally due to electrolysis, a flow of current would necessarily be involved. Conductivity (or its reciprocal, insulation resistance), ought therefore to parallel the rate of corrosion by various test samples. Accordingly, a series of measurements was made on fabrics of approximately 0.006 inch thickness as nearly alike as possible in density of weave, and all free from loading and sizing materials. The specimens were mounted on binding posts $1^1/_2$ inches center to center, and were conditioned for 48 hours at 120 degrees Fahrenheit and 90 per cent relative humidity before measuring resistance under those conditions. A parallel series of measurements was then made on the same fabrics after they had been exhaustively extracted with highly purified water. We believe that the results are sufficiently striking to merit including them (table I).

A glance over the trend of the insulation-resistance values for the unextracted samples might seem to indicate that the real explanation of corrosion was to be found here. However, when we pass on to the values for the extracted samples, we find that the enormous increases in resistance for rayon and silk completely refute the idea that corrosion parallels insulation resistance. For example, a 20-fold, or more, increase in insulation resistance by extraction results in no appreciable decrease in corrosive nature. There still remained the possibility that insulation resistance might decrease rapidly during the period of the corrosion test, but this was shown not to be so. It seemed impossible that the corrosion process could be independent of any flow of current, but our results indicated clearly that flow of current in itself was not the controlling factor.

Electrochemical Oxidation as a Cause of Corrosion

As a last resort, we attempted to test the possibility that electrochemical oxidation of cellulose, in the presence of water, might take place at the anode, and we were finally rewarded with the correct explanation of the observed copper corrosion. If the cellulose were oxidized at the anode, water-soluble organic acids would be formed and ought to be capable of detection. For test purposes, it was necessary to replace the copper wires by some metal which would not react with such acids. We therefore used platinum wires in contact with rayon and carried out the test in other respects exactly as the standard corrosion test described above. At the end of six days, the specimen of rayon was examined for chemical changes in the cellulose. By means of Harrison's reagent[1] it was found that the cellulose had acquired reducing properties throughout the whole area between the wires, indicating either hydration or oxidation. By means of indicators, it was shown that free acid was present only along a thin line which had been in contact with the positive wire. It is a commonplace fact that green copper corrosion always appears on the positive wire. Hence, the production of water-soluble acids at the anode offers an explanation of this corrosion which appears to be inescapable. Incidentally, it can readily be demonstrated on a large scale that cellulose is electrochemically oxidized to a complex mixture of water-soluble organic acids. By grinding up cellulose fibers and suspending them in water in an oxidation cell, large quantities of these acids may be obtained.

The above explanation of corrosion also offers an obvious explanation of the failure of exhaustive extraction to reduce appreciably the corrosive nature of paper or cellulose fabrics. If appreciable amounts of water-soluble acids are formed by the oxidation of cellulose, the presence or absence of traces of electrolytes in the original paper or cloth is quite unimportant. Therefore, as far as corrosion problems are concerned, extremely rigid specifications on paper or cloth probably do not accomplish anything useful. This does not imply, of course, that any low-grade material is just as good as a highly purified one, but merely that there is a definite limit to the usefulness of purification. The initial presence of large amounts of electrolytes is, of course, bound to have an effect.

Only in the case of cellulose has it been possible, by means of sensitive tests, to demonstrate under conditions to which radio coils are normally exposed, what actually takes place during the development of corrosion. The development of corrosive properties in protein materials may be largely or even altogether due to hydrolysis instead of oxidation. One might, therefore, tentatively specify as a noncorrosive material one which is nonelectrolytic itself and which is (*a*) resistant to oxidation and hydrolysis or (*b*) yields nonelectrolytic products.

Rubber is an example of the latter type, whereas the cellulose ethers and esters are quite resistant to oxidation. Apparently all that is necessary to increase enormously the resistance of the cellulose molecule to oxidation, is to replace the hydroxyl groups. It appears to be quite immaterial whether they are replaced by the acetate, nitrate, or any one of various other groups; the result is always a great increase in resistance to oxidation. Thus we find that any one of these cellulose derivatives is apparently satisfactory as far as corrosion is concerned, although cellulose acetate is the only practical possibility at the present time.

Mechanism of Copper Corrosion

During the corrosion of copper wires under a potential, the fundamental change that takes place is the oxidation of metallic copper to cupric ion ($Cu - 2e = Cu^{++}$). If we designate the negative ion which appears in combination with Cu^{++} as A^-, the compound may be written as CuA_2. The latter accumulates as a green cupric compound on the positive wire. The two prerequisites for the appearance of green corrosion are, therefore, oxidizing conditions at the copper wire and availability of a negative ion. It is obvious that the deficiency of electrons at the positive wire provides the oxidizing conditions, and if an electrolyte is present in the path between positive and negative wires, all that remains is to provide mobility for its ions. At high humidities, water which is absorbed, or adsorbed, by cellulose provides the medium in which the ions may migrate. In low humidities, that is, in the virtual absence of free water, corrosion is, in general, exceedingly slow.

It is obvious that the presence of any electrolyte which will yield A^-, will contribute toward the formation of the green product of corrosion, CuA_2. It is immaterial whether the electrolyte is an acid, HA, or a salt such as NaA. Thus, pH measurements are without significance in predicting or explaining corrosion, as a neutral salt may be at least as harmful as an equivalent amount of acid. In fact, if we are considering a very weak acid such as abietic acid and its salt, the latter will be much more harmful. The acid itself may be so weak or so insoluble, or both, that it will be practically un-ionized, whereas the salt will be highly ionized. It is a familiar fact that rosin itself has no corrosive action, whereas sodium abietate (rosin size) is highly corrosive.

Now to return to the specific case of cellulose, electrochemical oxidation will take place at the wire at which oxidizing conditions exist; namely, the positive wire. The organic acids formed by oxidation will thus make immediately available their negative ions, and conditions for formation of a salt, CuA_2, are complete.

If, however, we examine this mechanism of corrosion critically, we find that in order for corrosion to proceed by deposition of negative ions of organic acids on the positive wire, a corresponding flow of current would necessarily take place. This would require that corrosion be a function of conductivity and would appear to be in direct conflict with our finding that samples of cellulosic fabric, extracted and unextracted, respectively, show no correlation between rate of corrosion and conductivity. This conflict, however, may be apparent rather than real, for the reason which follows.

Suppose we examine two samples of cellulose fabric, one contaminated with a trace of active electrolyte and one exhaustively purified. The initial insulation resistance of the former will be greatly decreased, particularly in high humidities, by the presence of electrolyte; but one might expect that with continued application of potential, the electrolyte would be used up and the insulation resistance would rise to approximately that of the previously purified sample. This is actually what we observe experimentally. In addition, the disappearance of the contaminating electrolyte would leave the cellulose itself as the only remaining source of corrosive material, and one would expect that the continuing rate of corrosion would approximate that of the previously purified sample. Thus we see that the amounts of corrosion caused, respectively, by purified cellulose with a high insulation resistance and by material contaminated by electrolyte, will differ only by the corrosion caused by the contaminant. This might well be so small as to be unimportant.

Impregnation as a Protection for Corrosive Materials

In view of the high cost of cellulose-acetate films and cloth, it would be highly desirable to use paper or cotton as a base material for tape backing and impregnate or coat with some noncorrosive material. A number of attempts have been made to develop a practical construction of this type, but the result has been consistent failure. It must be borne in mind that a satisfactory material for the purpose must be sufficiently tough so that contacting wires will never penetrate the film of impregnating or coating material and come in contact with the cellulose. Such noncorrosive materials as paraffin, shellac, and other highly thermoplastic or excessively brittle materials are obviously inapplicable. Cellulose acetate itself is satisfactory, but as a matter of experience, such a heavy coat is required to give complete protection of the surface, that no economic advantage could be gained. In addition, when such material was slit, cut, or torn, cellulose fibers were exposed, thereby generating a region at which corrosion could take place.

To sum up, we feel that the most satisfactory and practical construction for a corrosion-free electrical tape is cellulose acetate coated with a good quality rubber-resin adhesive.

Discussion

B. W. Erikson (General Electric Company, Schenectady, N. Y.): H. N. Stephens and G. B. Gehrenbeck are to be congratulated on their masterly and timely solution of a very difficult problem. It is well-known to anyone who for years has been connected with the manufacturing problems incident to fine-wire coils that so-called corrosion failures have constituted the majority of all field failures.

The successful use in recent months of so-called noncorrosive material has plainly indicated that the writers have correctly analyzed the causes for fine-wire corrosion failures. Coils operated on an accelerated test at 100 per cent humidity in 40 degrees centigrade ambient over periods of months have conclusively proved that if the ordinary cellulose materials such as tapes and papers are excluded from the coil structure and acetate, mica, or asphaltic materials substituted the coils will last practically indefinitely. As a comparison, coils made with the best so-called acid-free cellulose materials on these accelerated tests seldom last beyond ten days, whereas the so-called corrosion-free coil construction shows a life expectancy of at least four months under these very severe tests. Our tests agree with the authors' that moisture is an essential factor in corrosion failures.

In relation to the paragraph on impregnation as a protection of corrosive materials it has been quite definitely shown that even three or four coats of a good baking varnish is not enough to protect against fine-wire corrosion. For this reason we agree with the authors that the only really satisfactory solution is the strict adherence to corrosion-free materials or in other words the exclusive use of cellulose acetate, mica, and asphaltic materials.

G. B. Gehrenbeck: Mr. Erikson lists three materials which he considers as corrosion free; namely, cellulose acetate, mica, and asphaltic materials. When tested across a flat unbroken surface, mica is indeed noncorrosive. However, when the test is made between two edges or along one edge, we have found rather low resistivity and some evidence of corrosion. Apparently, some electrolyte is present between the laminae of the mica, which under high humidity may carry an appreciable current. In a coil, there is always the possibility that the fine wires will come in contact with the edge as well as the face of the insulation. On this basis, mica appears to be less desirable for the insulation of fine wire coils than does cellulose acetate.

Contact Phenomena in Telephone Switching Circuits

A. M. CURTIS
NONMEMBER AIEE

Synopsis: The phenomena occurring at the closing and opening of contacts carrying weak currents have been investigated by means which include a study of the high-frequency transient voltages and currents. These influence the erosion in a complex manner which varies with contact materials, surface conditions, and surrounding atmosphere. Three principal classes of effect have been distinguished. These are: (1) Disruptive spark-overs initiating a series of metallic arcs lasting less than a microsecond each. (2) A nitrogen-gas glow discharge at about 300 volts, preceded by a brief group of disruptive spark-overs. (3) High field breakdowns due to cold point discharges which cause transient metallic closures of approaching contacts and similar transient reclosures of separating contacts.

THE operation of a telephone system depends on the proper performance of many millions of electrical contacts, a large proportion of which are in relays. The relays must be designed for a life during which they operate from as few as 5,000 to as many as 400,000,000 times. Although the nominal currents and voltages carried by the contacts are rather low, the large number of operations may cause erosion which in a very small percentage of cases leads to failures to close or open the circuit. The difficulties caused by even very rare failures make the control of contact erosion a problem of major importance for the telephone companies.

Research and development work on contacts has of course been carried on continuously since very early in the development of the telephone system. The aim is to design contacts to have a life at least equal to that of the apparatus of which they form a part and to require a minimum of maintenance. Although this aim has in general been successfully met there have been some cases in which the contacts have worn out too rapidly.

Although it has long been realized that contact operation necessarily involved the generation of high-frequency transients, there was at first no apparatus available which would permit these transients to be studied. The Dufour oscillograph was for a long time the only instrument which covered the range of frequencies involved. It was employed as early as 1926 in studies of contact sparking but it was very cumbersome in use, often introduced artificial conditions into the circuit of the contacts, and progress with its use was necessarily very slow. During the past few years rapid advances have been made in the development of glass-envelope cathode-ray oscillograph tubes. By employing the latest types of tubes, and combining them when necessary with wide-band high-frequency amplifiers and with circuits which permit synchronization of the tube sweep circuit with the contact operation, it has been possible to make thousands of observations in the time originally taken by a single oscillogram, and to cover the entire range of currents, voltages, and frequencies involved. We now have available means which will permit the visual observation of transient voltages at frequencies as high as 400 megacycles per second, and transient currents with components reaching 20 megacycles per second. Single pulses lasting a small fraction of a microsecond, and complex transients containing components as high as 5 megacycles can be clearly resolved and photographed while the envelopes of still higher frequencies can be recorded.

In order to study the transients at contacts operating at 50 volts and steady currents under one ampere, in common types of telephone circuits, voltages as high as 2,000 and currents reaching 20 amperes must be within the range of the apparatus. A detailed description of the apparatus will not be attempted in this article, but the results of observations made with it and photographs of the more significant transient components will be presented.

Paper 40-53, recommended by the AIEE committee on communication, and presented at the AIEE winter convention, New York, N. Y., January 22-26, 1940. Manuscript submitted November 8, 1939; made available for preprinting January 6, 1940; released for final publication February 17, 1940.

A. M. Curtis is with the Bell Telephone Laboratories, Inc., New York, N. Y.

The author wishes to acknowledge the collaboration of E. T. Burton in the observation and explanation of the phenomena and the assistance of I. E. Cole in the development of the testing apparatus; of Mr. Glass, who developed the cathode-ray tubes; and that of many engineers and physicists in our organization, in particular Messrs. Mathes, Hogg, Goucher, and Pearson, in the formulation of some of the hypotheses expressed.

Study of the currents requires an amplifier as an impedance matching device and some circuit conditions make a shielded input transformer necessary. An input impedance of from 0.5 to 2 ohms, a voltage gain of about 75 times, and a substantially flat characteristic of output versus input from 20 kilocycles to 20 megacycles are usually employed. Lower frequencies may be observed with other amplifiers and the range from zero to 10,000 cycles per second is studied by means of the "rapid record" oscillograph.

With earlier cathode-ray tubes, beam currents of 40 microamperes at 5,000 volts were employed. The latest tubes give a beam current of about one milliampere at this voltage. A Leica camera with an $f/1.5$ Xenon lens and ultraspeed panchromatic film has been used in most of the photographic work. The photography is complicated by the presence in a single transient photograph of some components in which the beam speed may be a thousand times as fast as it is in others. However, beam speeds in excess of 200 kilometers a second are photographed, and a continuous sine wave of 5 megacycles frequency may be clearly resolved on a single transit. Sweep speeds which permit resolution of much higher frequencies are employed for visual observation, where the transient component being studied can be found by frequent repetition of the contact operation. As the occurrence of a particular component varies in time of its position in the entire transient, very high sweep speeds are impractical for photography as a prohibitively large proportion of exposures would be blanks. A sweep speed of about 15 kilometers per second is about as high as is useful except in some special cases.

We may commence the discussion by setting up what appears to be a very simple circuit (see figure 1), a pair of contacts, one of which is connected by a length of wire to a relay winding, which is in turn connected to one pole of a 50-volt battery. The mate contact and the other pole of the battery are grounded by very short wires. The oscillograph is arranged so that the voltage between the contacts and the current through them can be observed, great care being taken to insure that the added apparatus does not appreciably change the circuit characteristics even at very high frequencies. A low-power microscope may be set up to observe the operating area of the contacts.

When the contacts close, the first thing that happens is the discharge of the relay structure (a capacity) and of the wire through the contacts. The wire may be thought of as a radio antenna, more or less open-circuited at the load relay-winding terminal, and either grounded or opened at the contacts. The wire forms an oscillatory circuit of moderately heavy damping with a surge impedance of about 100 ohms. As it is charged to 50 volts, when the contacts come together an oscillation having a peak current of 0.5 ampere occurs, and is over before the steady current through the relay winding has more than started to build up. The frequency of the line oscillation depends on the length and other characteristics of the wire, but it is (in the telephone plant) rarely lower than 500,000 cycles, and on short leads it may be many megacycles. Fortunately most contacts are not much affected by closing a half ampere. Erosion and build-up will occur, but at rather slow rates, and they are usually completely obscured by effects due to the contact opening. Of course, if the contacts bounce,* the effect will be more complex, but we are assuming for the moment that they do not bounce. The structure of the relay itself, including the pair of springs separated at its base by an insulating sheet, is also an oscillating circuit. We have not been able to get inside of this circuit and measure the current surge but its oscillation frequency seems to be about 250 megacycles for certain telephone relays.

Now suppose that the simple circuit of our closing contacts is complicated by an additional wire connected to the contact-spring terminal. This is also charged to 50 volts before the contacts close, and being a second circuit of a hundred ohms surge impedance in parallel with the original wire, the current peak discharged through the contacts will now be about one ampere. But now the contacts are likely to act differently.

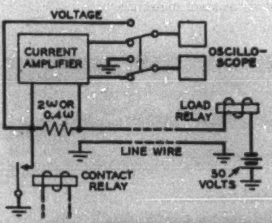

Figure 1 (left). Typical relay and contact circuit

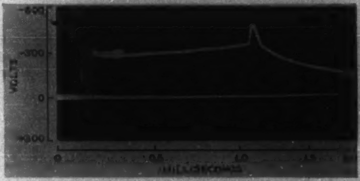

Figure 2 (right). "A" transient starting with metallic arc (voltage)

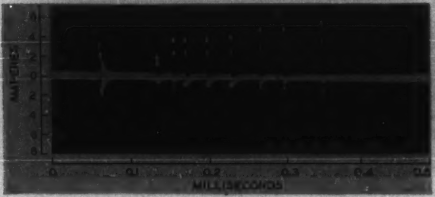

Figure 3. Entire "B" transient (voltage)

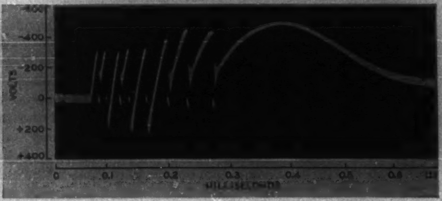

Figure 4 (below). Entire "B" transient (current)

---

* Bounce, as distinguished from chatter, reopens the contacts after several thousandths of a second.

About a microsecond after the current reaches its peak, but before the charge in the wires has been completely dissipated, the circuit is interrupted and the discharge stops. A spark, which is visible in the microscope, suggests that the current-carrying areas have been exploded and blown apart. A few microseconds later they again close and the rest of the energy is discharged, but some of the contact metal must have been destroyed.

If several "idle" wires are attached to the contact, the current surge, and the number and duration of the contact reopenings increase, but not usually in direct proportion to the number of wires. If the idle wires are attached to the load relay-winding terminal instead of to the contact, the current is smaller, as the length of single wire from relay winding to contact is effectively in series with them.

In the telephone relay circuits which we are considering, the steady-state current plays little part during contact closing if the contact-carrying relay is properly adjusted, as the contacts come to rest while the current is still held at a small fraction of its final value by the inductance of the load relay winding.

Under some conditions which are more likely to occur in telegraph than in telephone circuits the contact closure phenomena are somewhat different than those described above. Assume, for example, that the potential between the open contacts may be adjusted in a range between 30 and 250 volts while the final direct current is limited by circuit resistance to less than 0.5 ampere. At the low voltage, observations of the current and voltage transients indicate that the closing contacts merely discharge the line. As the voltage is raised so that the current surge peak is in the range between 0.5 ampere and 1 ampere the reopenings, due presumably to overheating of the contacting areas by the discharge, are observed. These become more frequent as the voltage and current increase, and a new type of current surge begins to appear. This is placed on the time axis ahead of the point at which the initial closures have been occurring (usually five to ten microseconds earlier) and consists of one or more irregularly spaced heavily damped pulses of current lasting only a small fraction of a microsecond and evidently discharging only a minute amount of the energy stored in the system. They occur perhaps once in a hundred closures at 30 volts, nearly every closure at 100 volts, and several for every closure at 250 volts. It is believed that the transients observed indicate the formation of minute metallic bridges[1] between the approaching contacts due to a softening of the metal by a cold point discharge and its deformation by the static field, and that once formed they are exploded by the discharge of current from the relay structure and adjacent wiring. The high fields necessary for phenomena of this type are of course due to the minute distances as the contacts approach final closure. A good deal of the erosion on telegraph-relay contacts operating on capacitative loads or shunted by resistance-capacity "spark-killer" circuits is probably due to these "preclosures," but they are not thought to be of much importance at the lower battery voltages of the telephone plant.

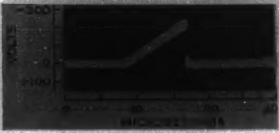

Figure 5. Initial opening and reclosure—"B" transient (voltage)

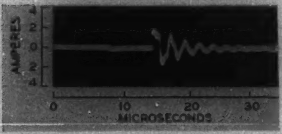

Figure 6. Initial opening and reclosure—"B" transient (current)

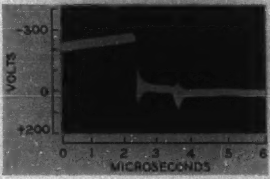

Figure 7. Initial opening and reclosure—"B" transient (voltage) rapid sweep

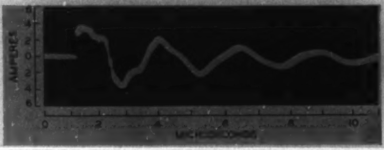

Figure 8. Initial opening and reclosure—"B" transient (current) rapid sweep

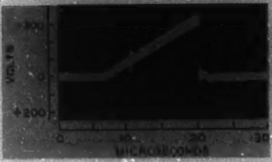

Figure 9. Evidence of point discharge (voltage)

Having now described the phenomena as contacts close in a doubtless oversimplified manner, we may consider that they have been closed for a long time, the direct current and the magnetic field of the load relay are established, and the contacts are to be separated. The action now becomes really complicated and much of it is as yet only surmised. Several different things may happen, and these are influenced by humidity, dirt, surface films, absorbed gases, and many other factors, including the speed of contact separation, the roughness of the surfaces, and the presence or absence of a wiping motion as well as the physical properties of the contact materials.

If the steady current exceeds certain well-known values ranging between 0.4 ampere and 1 ampere, characteristic of the contact materials, a metallic arc is formed as the contacts separate.[2] This is maintained at an initial potential of about 15 volts, and increases to a final value usually below 30 volts. The arc may last several milliseconds, but when it breaks it is followed by a complex transient lasting possibly another millisecond. These transients may be of two general types to be described later. This case is not of much importance in the telephone plant as the steady current is ordinarily kept below the value at which prolonged arcing occurs.

Metallic arcs lasting several ten-thousandths of a second, and also followed by complex transients, may occur in breaking steady currents considerably less than those ordinarily believed to cause arcing. The effect of these transient

---

[1] For all numbered references, see list at end of paper.

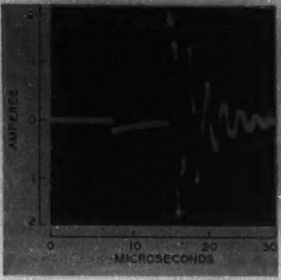

Figure 10. Evidence of point discharge (current)

arcs on contact life has not been studied separately, but they can hardly fail to increase the erosion. Their effect is unavoidably included in the studies of contact life in the higher range of d-c values. Figure 2 shows the voltage between a pair of opening silver contacts in which the steady current (0.25 ampere) is strong enough so that a brief metallic arc (indicated by the upward deflection of the trace to a new horizontal position) precedes the final transient.

If the steady-state current is low enough so that neither prolonged nor brief metallic arcs are formed at the initial contact separation, one of two general types of complex transients occur, or both types may be mixed. These have been designated the *A* and *B* types. The *B* type transient seems to be the more normal and it is difficult, probably impossible, to set circuit and contact conditions which will never give a *B* transient. It is identified by a bright spark between the contacts, showing in a spectroscope bright lines of the vaporized metal, and consists of a series of disruptive spark-overs at gradually increasing voltages. Each spark-over is individually very complicated. The appearance of the contacts during the *A* type transient is radically different from that during the *B* transient. There will be a minute bright spark, surrounded by a violet cloud which spreads out from the immediate contact area over the negative contact, and sometimes travels as far as a sixteenth of an inch from the working area.

As a result of thousands of observations of the transient currents and voltages, and many experiments, and discussions with several physicists and engineers with whom the writer is associated, a plausible explanation of the phenomena has been arrived at and will be given as at least a working hypothesis.

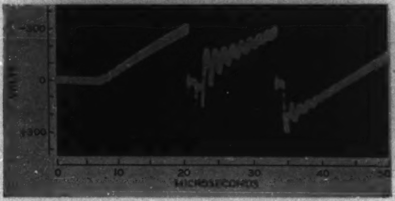

Figure 11. Early part of "B" transient (voltage)

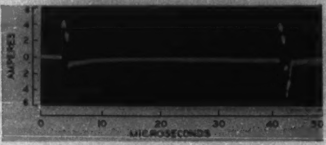

Figure 12 (right). Early part of "B" transient (current)

The voltage wave form of an entire *B* transient, covering the time from the initial separation of the contacts to the final subsidence of the voltage charging the line wire is shown in figure 3, and the a-c components of the current in the range from 20 kilocycles to 20 megacycles are shown in figure 4. The low-frequency components of the current are comparatively weak. A line and load relay were chosen to give a relatively simple transient with the important components at frequencies which could be photographed. A 500-ohm Western Electric U-type relay and a line of 300 feet of number 22 switchboard pair were used. The mate wire of the pair was grounded at both ends. The currents and voltages were not photographed simultaneously but the types of the transients were correlated by repeated observations. A current picture will not exactly correspond to a voltage picture, as the transients produced by successive operations of a contact are never identical.

The *B* transient may be explained as follows, using as a basis the simple circuit of figure 1. The steady current is established and the contacts start to separate, moving apart at a speed, which is at first surprisingly slow (about an inch a second). The contacts have been deformed by the pressure between them, and as this is relaxed, the current density and the temperature at the contacting areas rapidly increase until at some light pressure the area becomes so small that the current explodes it. There may be some necking out of the softened contacts before this and under some conditions there are indications of a metallic arc lasting a fraction of a microsecond, but at any rate, an initial rupture occurs between hot and soft metal areas.

The wire has been at ground potential, but the battery plus the collapsing magnetic field of the load relay commence to charge it at a rate depending on the line and relay-winding capacity and the relay inductance and losses. In 10 or 20 microseconds, it has reached at the contacts a potential of from 50 to 200 volts. This is below the voltage at which spark-over due to ionization of the air can occur, but something usually happens which recloses the circuit. This is believed to be caused in somewhat the same manner as the "preclosures" mentioned earlier. It is probable that a cold point discharge reheats the contacts. This is followed by a collapse of the voltage to about 15 volts above zero in the direction of the previous voltage, indicating the formation of a metallic arc. This lasts a fraction of a microsecond and the voltage then drops to nearly zero, suggesting that the contact areas heated by the field current and the arc have been drawn together in solid metallic contact. The line is discharged with an oscillation of comparatively low damping (which is characteristic of the line wire) reaching a current peak usually ranging from 0.5 to 2 amperes. The first cycle of the oscillation is distorted by the higher resistance of the path to ground caused by the arcing stage in the reclosure. After a few microseconds the

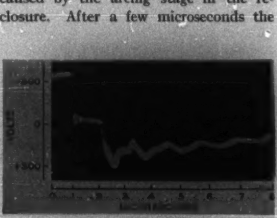

Figure 13. Single spark-over of "B" transient with single arc (voltage)

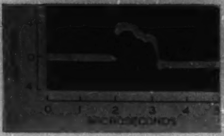

Figure 14. Single spark-over of "B" transient, with single arc (current)

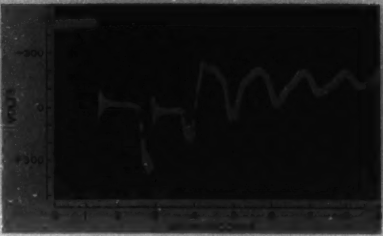

Figure 15. Single spark-over of "B" transient, with double arc (voltage)

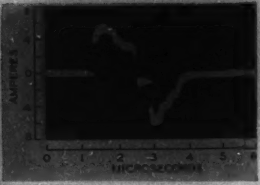

Figure 16. Single spark-over of "B" transient, with double arc (current)

contacts are opened a second time by the continued motion. Occasionally they reclose a second time but they usually stay open until the voltage has built up by the continued discharge of the load relay inductance to a value between 300 and 350 volts. Then a spark occurs at what is usually considered the minimum sparking potential between contacts in air.

Figures 5 and 6 show the voltage and current of the initial opening and reclosure of the contacts at the start of a *B* transient. The brief arc at initial opening is barely detectable in figure 5. Figures 7 and 8 show similar voltages and currents at an increased sweep speed. In figure 7 the metallic arc established during the reclosure is plainly evidenced by the collapse of the voltage to about 15 volts and its maintenance at this value for about a microsecond before it drops to zero. The effect of the arc in distorting the oscillating discharge of the current from the line wire is evident in figure 8. The current oscillation of figure 8 may be duplicated merely by charging the line wire to a suitable voltage through a high resistance and closing the contacts, the far end of the line being grounded through the load relay and a large capacitor which replaces the usual battery.

It is likely that the point discharge precedes the arc on reclosure by such a short time that it cannot ordinarily be resolved. Nevertheless disturbances of the voltage and current are occasionally found which seem to indicate that a discharge path formed and was checked (possibly by melting off the point) without establishing an arc or metallic bridge. Such a disturbance of the rising voltage is indicated in figure 9 by a high-frequency oscillation about five microseconds after the first rise of the voltage trace. Figure 10, which shows the current of the second of two initial reclosures, indicates a similar phenomenon. Five microseconds after the rupture of the circuit, shown by the downward deflection of the zero line, a dim line upward records a current surge lasting a fraction of a microsecond and reaching about three-fourths ampere. This surge however did not result in the immediate formation of an arc which was established about five microseconds later.

The initial separation of the contacts does not always result in a metallic reclosure. Figure 11 shows the voltage of the early part of the *B* transient. Here the first collapse of the voltage is a spark-over from about −300 volts which establishes an arc at about −15 volts. This arc is broken and as the line is not completely discharged, the voltage between the contacts rises to about +140 volts; a second arc is established at +15 volts and broken in its turn. Possibly because of the continually increasing distance, the arc is not re-established, and the voltage builds up with oscillations of a frequency characteristic of the line wire insulated at both ends until it reaches −300 volts a second time and another spark passes. This time only one arc is formed, and the recovery of the voltage starts from the positive side of the zero axis. The current surges corresponding to the voltage collapses of figure 11 are shown in figure 12. Here the first pulse represents a spark-over which formed only one arc. As the current from the line reached about four amperes it was checked and the conducting arc was broken (possibly by being extended laterally into the region of cooler metal). The second pulse shows the current of a spark-over which formed two arcing periods.

These phenomena are shown in more detail in figures 13 and 14 which show the voltage and current of a spark-over forming only one arc, and 15 and 16 which show the wave forms when two arcs are formed. Note that the frequency of the current oscillation is that of the line grounded at one end only (the impedance of the load relay being high at this frequency) and is about half that of the voltage oscillation which is that of the line open at both ends. Oscillations of both frequencies may be found in the line at a distance from either end.

Corresponding observations may be made of the occurrence of 3, 4, and 5 arcing periods, the pattern followed being about the same. The higher the voltage at spark-over the more arcing periods;

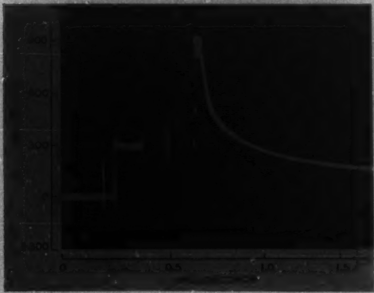

Figure 17 (left). Typical "mixed A and B" transient (voltage)

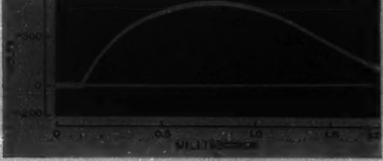

Figure 18. Effect on voltage transient of changing wire-line length—1,100 feet

an odd number of arcing periods is followed by a recovery of the voltage from the opposite side of the zero axis from that of the voltage before spark-over, an even number by recovery from the same side of the zero axis. The arcing periods are individually complex, having superposed on them oscillations believed to be due to the relay structure and the leads to the oscillograph which are too fast to be resolved photographically by the means available. These oscillations may be observed visually by using higher sweep speeds and reach frequencies of 250 megacycles.

While the arcs ordinarily do not exceed a microsecond in duration, they are probably an important factor in determining contact erosion, as several hundred may occur at each contact opening.

As may be seen from figure 3, the spark-overs continue to occur, the successive voltage breakdowns corresponding to the normal sparking potential as the contact separation increases with time (with some irregularities due to residual ionization in the gap) until the separation is finally so large that the energy remaining in the load relay cannot charge the line to the breakdown voltage. At this stage the line discharges slowly back through the load relay to the battery voltage. The peak voltage reached may be as high as 2,000 volts.

The principal characteristics of the *B* discharge can be produced by a simple experiment which does not use a load relay. The transient is not dependent on a load inductance, but only on a source of voltage which will charge a wire at a sufficiently rapid (but not too rapid) rate while a pair of contacts, which initially ground the wire, are separating. If a wire about 100 feet long is connected to a source of somewhat more than 350 volts through a resistance of from 5,000 to 20,000 ohms, and is also grounded by a contact at one end, a transient is produced when the contacts open which shows the characteristics of a *B* type transient except the final dying away of the voltage to 50 volts.

It must not be understood that every spark transient is purely of either the *A* or the *B* type. It is very common for the *A* type transient to break down into the *B* type and less often the *B* transient establishes the gas glow discharge for a brief period in the middle of the spark-overs.

A "mixed" transient is shown in its entire duration in figure 17. Here, after a group of spark-overs, a period in which the voltage is maintained steadily at about 300 volts for about 0.0002 second intervenes, and is followed by more spark-overs from considerably higher voltages. In order to produce this transient the length of the line wire was reduced to ten feet, at which length and with a 1,000-ohm load relay the tendency is to produce intermittent groups of *A* or *B* transients, interspersed with the mixed type shown, when the relay is operated frequently.

The number of spark-overs in each *B* transient varies with the circuit conditions. As many as a thousand may be found with a load consisting of a number of relays in parallel on a wire of moderate length and as few as one in the limiting case.

While the occurrence of the *B* transient is favored by long line wires and high-impedance relay loads, beyond a certain length which with telephone relays and wiring is from 300 to 2,000 feet (the longer lengths being associated with the lower impedance relays) no spark-overs at all occur. The voltage build-up is so slow that the spark-over potential is not reached at any time during contact opening and the contacts may be said to be protected by the line wire. The series of voltage oscillograms, figures 18 to 24 inclusive, shows the change from a smooth transient with no spark-overs through the *B* type with an increasing number of spark-overs to the final *A* type. The *A* type transient of figure 22, which has superposed on the 300-volt gas glow discharge stage a relaxation type of oscillation, the *B* transient of figure 23 and the simple *A* transient of figure 24, were all produced under identical conditions in quick succession. The change in characteristics from figure 18 to figure 24 was produced merely by a

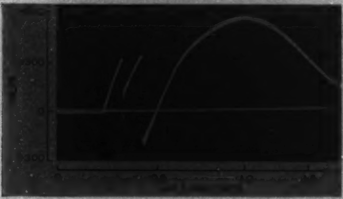

Figure 19 (left). Effect on voltage transient of changing wire - line length—600 feet

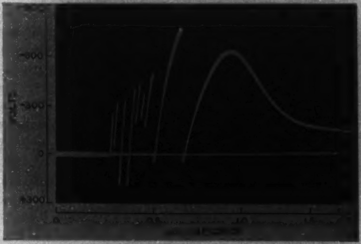

Figure 20 (right). Effect on voltage transient of changing wire-line length—150 feet

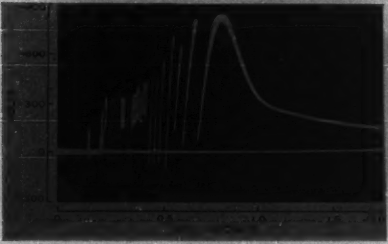

Figure 21 (left). Effect on voltage transient of changing wire-line length—50 feet

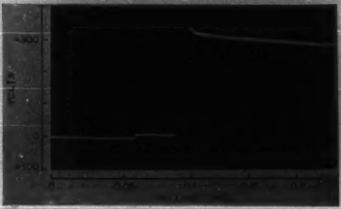

Figure 22 (right). Effect on voltage transient of changing wire-line length—10 feet reduction in the length of the connecting wire from 1,100 feet through three intermediate stages to 10 feet, a 1,000-ohm load relay being used. This explains a puzzling effect noted with many contact materials. With a supposedly identical circuit, the erosion will be small with very short wires, increase rapidly as the wiring length increases, and then decrease again becoming very small with very long wires.

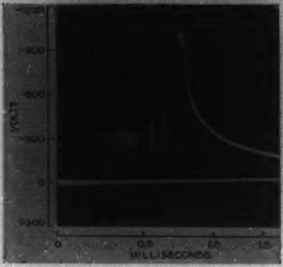

Figure 23. Effect on voltage transient of changing wire-line length—10 feet

The *B* transient is more frequently observed with freshly filed contacts, at high humidities, and with a rolling or wiping motion of the contacts in opening. It is always found if the contacts are of oxidized metal or operate in an oxygen atmosphere. In fact, there seem to be good reasons for believing that its production is bound up with the presence of oxygen on or in the surface of the active contact metal.

It may be seen from the last series of oscillograms that if the circuit and the conditions of the contact surfaces are just right, the *B* transient is replaced by a much simpler and less stable type, the *A* transient. It will occur usually when the wiring is short or the load relay is of low impedance, with contacts which have been operated until the original surface has been burned off and have not stood idle more than a few minutes. It starts much as does the *B* type, but after a dozen or a hundred spark-overs from about 350 volts, which come much closer together in time than those of the *B* transient, the voltage becomes steady at about 300 volts. This condition lasts for perhaps 0.6 millisecond, then the voltage rises to about 400 or 450 volts and gradually reduces, reaching the battery voltage after several milliseconds. A typical *A*-type transient is shown in figure 24. It is suggested as a hypothesis that during the spark-over stage, the oxygen is being exhausted from the surfaces of the current-carrying areas of the contacts by burning the metal and that when this has been completed, a nitrogen-gas glow discharge is formed and maintained during the rest of the contact opening, if the supply of energy from the load inductance through the line is rapid enough to prevent the voltage from dropping below about 280 volts.

The glow-discharge phase of the *A* transient is unstable. If transient voltages induced by the operation of relays in other circuits reach the contact gap during the time that a sustained glow discharge is attempting to form, its formation is interfered with and a mixed or *B*-type transient results. Occasionally as illustrated in figure 22 the glow discharge of the *A* transient has superposed on it a saw-toothed oscillation of from 10 to 50 volts peak-to-peak. Part of an *A* type transient showing this peculiarity is illustrated by the oscillogram of figure 25. This appears to be a relaxation oscillation such as is commonly produced in ionized-gas tubes, riding on the normal 300-volt axis of the gas glow discharge. The conditions which lead to the occurrence of this oscillation at atmospheric pressure have not been identified, but it is found to be quite stable in some cases where contacts have been sealed in a mixture of air and gases at about half atmospheric pressure.

A typical *A* transient is shown in detail in figures 26, 27, and 28. The circuit consisted of a 250-ohm relay connected to the contacts by ten feet of wire, the battery being 50 volts as usual. Figure 26 shows the voltage of the early part of the transient during which rapid spark-overs are interspersed with two brief periods during which a gas glow discharge was established but not maintained. Figure 27 shows the final spark-over before the establishment of the glow discharge at about 300 volts. A group of the current pulses corresponding to the initial part of the spark-over stage is shown in figure 28. These are complicated by the line oscillations (which should be of about 30 megacycles frequency) and appear to last less than 0.1 microsecond.

It may be seen that the individual spark-overs at the start of the *A* transient are somewhat different in form from those of the *B* transient. The voltage reaches 320 volts in a microsecond or so, and in some cases collapses to zero or beyond immediately. There are sometimes indications of arcing periods lasting much less than 0.1 microsecond and the voltage recovers with oscillations of the line wire but the duration of the phenomenon is too brief for very accurate analysis. But in many cases, the voltage having reached its peak, drops to an intermediate value of 280 volts and recovers to 320 volts before it collapses. This is probably due to the temporary formation of the nitrogen glow discharge, which is finally established and maintained during the remainder of the contact opening when for some reason the spark-over does not occur. In cases where the contacts are on the verge of producing a *B* transient the voltage may rise to 500 volts and then collapse to the 300 volts of the gas glow discharge.

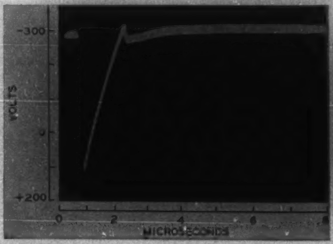

Figure 24. Effect on voltage transient of changing wire-line length—10 feet

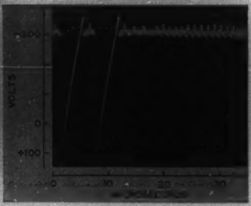

Figure 25. Oscillation on glow discharge of "A" transient (voltage)

It is very interesting to set up a circuit which will cause the *A* transient to predominate, and start operating freshly filed contacts several times a second observing the transient voltage at contact opening on the oscilloscope. The first transient will always be of the *B* type. Usually the first few dozen will also. However, after a while one of the transients will show a flat top at about 300 volts for a very brief period and this tendency increases until finally a complete *A* transient occurs. After this, the *A* transients become more and more com-

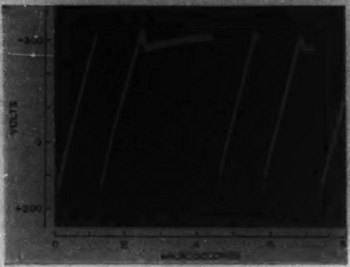

Figure 26 (left). Start of "A" transient (voltage)

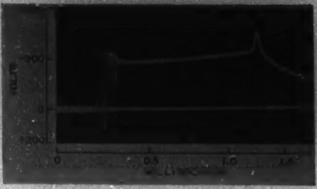

Figure 27 (right). Start of stable glow discharge of "A" transient (voltage)

mon until finally the *B* transients occur perhaps once in a hundred openings. If then a gentle stream of oxygen is blown on the contacts, only *B* transients will occur until a few seconds after it has been turned off. Blowing the breath on the contacts has a similar but less definite effect, while a stream of dry compressed air has no effect.

If on the contrary the circuit conditions are selected so that *B* transients predominate, a stream of nitrogen will induce *A* transients. That is, *A* transients are not found in oxygen and *B* transients are rare in nitrogen.

If instead of operating the contacts several times a second they are operated at longer intervals, the tendency to produce the *A* transient is reduced. When contacts are operated in air a certain interval between operations can be found which causes all transients to be of the *B* type. This probably depends on humidity and also on circuit conditions and contact material. In one experiment, a wait of 45 seconds between operations gave all *B* transients with silver contacts, while a wait of five minutes was required with palladium contacts. This is possibly due to a different rate of film formation.

Life tests on palladium contacts show much lower erosion with *A* transients than with *B* transients. The effect of the two types of transient in terminating the life of silver contacts is not markedly different. The contours of the eroded surfaces exhibit a wide variety, and it is not easy to correlate the transient type with its effect. It is evident, however, that areas of the contacts which have never been in the d-c path may be severely eroded.

When we consider that the *B* transients produce oscillations in the line wires reaching several hundred volts and often 15 amperes, it is not to be wondered at that clicks will be produced in circuits in the immediate neighborhood of unprotected relay contacts. The *A* transients produce much weaker currents than the *B* transients and many contacts on successive operations will produce *A*, *B*, or mixed types. This explains the common observation that relay clicks vary over a wide range of amplitudes. The arrangement of telephone circuits in which the cabled wiring always contains a large number of grounded conductors, and is often enclosed in a lead shield, prevents any appreciable free radiation of the spark transient oscillations.

With the foregoing information available the contact erosion process at opening contacts appears briefly to be as follows. At very minute separations high field strengths exist even for moderate voltages. The resulting cold point discharge is often followed by a metallic arc which softens a tiny point on the contact which is pulled out and fused into metallic contact under the action of the high fields. After rupture by increasing separation or increasing current density, the process may repeat or, as is more likely, the separation is too great for another metallic bridge to form. The high field discharge then sets the stage for the next type of conduction or breakdown. This may be either a series of spark-overs interspersed with metallic arcs of extremely short duration or a gas glow discharge, initially intermittent and then more or less stable. Factors predisposing toward one or the other type of discharge are known thus far only in a most general fashion and much remains to be done before the relation between contact erosion and the transient currents and voltages can be predicted accurately. There is ample evidence that molten metal may be expelled from the immediate contact area at high velocity and may be deposited at distances of at least 0.1 inch. It also appears that both the ionized nitrogen cloud of the *A* transient and the disruptive sparks of the *B* transient may corrode the contacts and their supports at locations and distances which never enter directly into the rupture of the current path.

We have seen that the line wire contributes to the current surges through contacts due to its properties as an oscillatory circuit, charged repeatedly by the energy stored in the magnetic field of the relay. The surges and the resultant erosion may be reduced in several ways. If a radio-frequency choke coil is connected between the contact and the line wire, the discharges of the latter are much reduced, and the *A* type gas glow transient favored. A group of many current surges of 15 amperes peak may in most cases be reduced to one or two of 0.15 ampere or less, and a radical reduction in erosion secured. Unfortunately choke coils are expensive and inconvenient. The usual line wire may be terminated in approximately its surge impedance by shunting both ends to ground with a resistance of about 100 ohms in series with a capacitor of the order of 0.01 microfarad. This heavily damps the line oscillations and greatly reduces the number and severity of the current surges. It is also expensive. Instead of the copper line wire, a material such as iron or Permalloy-plated copper having a high surge impedance and large high-frequency a-c losses may be used. This seems more practical, but brings up new problems in design, handling, and soldering.

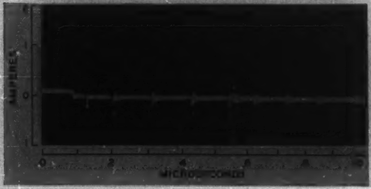

Figure 28. Start of "A" transient (current)

The most effective means of reducing erosion is of course the well-known "spark-killer" (consisting of a capacitor and resistance in series, shunted across the contact or load), which can be designed to hold the voltage below the spark-over point at least until the contacts have separated a safe distance.

When the conventional spark-killer is used it is generally assumed that what sparking then occurs is due to the discharge of the capacitor when the contacts close, provided that the spark-killer prevents the voltage at contact opening from reaching 350 volts. Unfortunately the "reclosure" effect described earlier appears unless the initial rise of voltage as the contacts separate is held down to a value considerably below the sparking potential by a suitable choice of the resistance in series with the spark-killer capacitor. If the rate of increase of the initial voltage in relation to the speed of separation of the contacts exceeds a figure which seems to depend on the contact material and the condition of its surfaces, the high-field point discharge comes into play and causes the separating contacts to reclose metallically while they are still at a minute separation and moving apart very slowly. In "reclosing" the line wire and capacitor are discharged, the current explodes the minute metallic bridge, producing a visible spark, and the circuit is thus reopened. This may occur a dozen times in some cases before the contacts finally stay separated. The higher the voltage which the spark-killer permits the more likely are the reclosures to take place, and the larger the number of reclosures at each contact opening. However, reclosures are usually not very common in cases where the voltage of the wave front is held below 50 volts. In the majority of cases in the telephone plant it is possible to do this without incurring much of a penalty due to erosion of the contacts on closing by the discharge of the spark-killer capacitor.

This discussion is not more than sufficient to serve as an introduction to the problems of contact sparking as revealed by the improved observing technique used in this study. Only the simplest cases have been considered, and the telephone plant is far from being simple. Many relays have multiple windings or metal sleeves, and multiple connections to the contacts are very common. As these complications considerably modify the contact spark wave form and erosion, each contact with associated circuits presents its own problem. The solution of these problems involves the careful study of circuit characteristics of a type which are ordinarily left to the radio engineer, as well as of the mechanical, chemical, and metallurgical properties of the contact materials.

Discussion

E. E. George (Phoenix Engineering Corporation, New York, N. Y.): The paper under discussion contains considerable material of a fundamental nature. This subject apparently has not been discussed previously before the AIEE. The paper answers many questions but raises many more and it is to be hoped that further work on the same subject will be published in the future.

Various relay engineers working with high-speed relays or with long cable circuits for pilot-wire protection or remote control, have run into numerous difficulties resulting from transient phenomena. It would be interesting to know whether the author has found any effect on relay operation other than contact deterioration. It seems that sensitive high-speed telegraphic relays should be affected by the transient currents observed by the author. In power-relay practice, a neon lamp with a high series resistance is frequently shunted across open relay contacts to act as a circuit monitoring device. It would be interesting to know the effect of this lamp on contact operation. It would also be interesting to know whether there is a critical maximum battery supply voltage or length of circuit beyond which trouble is likely to be experienced on pilot-wire circuits.

This paper may explain some of the difficulties frequently observed in trying to use very small d-c supervisory currents on pilot-wire circuits—currents under ten milliamperes.

The author makes reference to so-called "spark-killer circuits" consisting of a capacitor and series resistance, and it would be helpful to give some formula or basis for selecting the proper values of capacity and resistance for such circuits. In the past, it has been the practice of most engineers to consider contact operation perfect if there were no visible sparking. The author has contributed much to a better understanding of contact operation and his paper might well be required reading for all relay engineers.

A. M. Curtis: The principal effect of contact sparking transients aside from erosion is in causing contact sticking and consequent failure of the relay to open its circuit. It is possible to conceive of circuit conditions where the cross fire from a lead through which the steady current and transients of a telephone-type relay flows might cause brief operations of a very sensitive relay connected to another lead in the same cable. The principal difficulty from the contact sparking transients would be expected in cases where the induced currents reached the sensitive relay through a rectifier and particularly if the latter should be of a type where the very strong but very brief induced currents might be stored and discharged more slowly. It is hard to make a mechanical relay operate on a pulse only a thousandth of a second long.

A neon lamp shunted across relay contacts gives considerable protection, particularly if the series resistance is not too high. However, this is not as good as a proper spark capacitor as the delay in breakdown of the gas lamp may be 50 to 100 microseconds. During this period the voltage between contacts usually rises high enough to permit several spark-overs.

There is a complicated relation between contact material and battery voltage which has an important influence on the performance of contacts, especially those which work into capacity loads or are protected by capacity spark-killers. Generally it pays to keep the voltage low. Many contact materials which work well between 25 and 50 volts will be unsatisfactory at 150 volts.

I do not know of any general formula which can be used to design spark-killers. They fall into two general classes and some simple guiding principles can be stated.

If the steady current through the contact is above the arcing current of the material it is desirable to keep the voltage at the first opening of the contacts below the arcing voltage. This indicates about as large a capacitor as can be afforded and a resistance at least as low as $R=10/I$. But this leads to a situation where the discharge of the capacitor through the closing contacts may do more damage than the arc which is prevented and a compromise must be made by increasing the resistance to a value where the transient arc is no more troublesome than the capacitor discharge. This, of course, depends on the battery voltage and is another reason for keeping it low.

If the steady current is below the arcing value for the contact materials, the resistance for the best performance should be high enough to prevent the capacitor discharge currents through the closing contacts exceeding about one-third ampere, and low enough to limit the voltage at first instant of contact opening to about 50 volts. That is, it should be higher than $R=3E$ and lower than $R=50/I$. The first condition guards against explosive reopening of the contacts at closure; the second avoids reclosures on opening (always assuming a sufficiently large capacitor). But at the higher battery voltages and currents it is not possible to meet both conditions and in these cases a compromise must be again made. The capacitor should be large enough to keep the surge voltage from reaching 300 volts until after the contacts have separated about 0.002 inch. With many relays this takes about a quarter of a millisecond after the contacts have first started to separate. The capacity required varies with the relay. With a high-resistance relay 0.1 microfarad may be enough. One microfarad is enough for the general run of telephone relays but some heavy-duty electromagnets may require several microfarads.

The Application of Traction Motors

F. E. WYNNE
FELLOW AIEE

G. M. WOODS
NONMEMBER AIEE

Synopsis: The application of traction motors is based fundamentally on speed-time curve calculations. This method has been used for many years and is familiar to electrical engineers engaged primarily in transportation activities. Many other engineers infrequently encounter problems of traction-motor application but are not conversant with the effect which variations in service conditions produce on vehicle performance. This paper points out certain recent changes in transportation requirements tending toward greater standardization of equipment, and summarizes the effects of varying operating conditions. The broad basis of economical application is indicated.

THE application of all types of traction motors is based fundamentally on the speed-time curve. Speed-time curve calculations may be unnecessary for many specific applications, but a knowledge of the principles is essential to correct application of motors. The methods of calculation are covered fully in textbooks and for many years have been included in college courses in railway engineering. The purpose of this paper is to illustrate the application of the principles and show the effect on traction-motor performance of varying the more important determining factors.

In the past few years the business of electric transportation has undergone important changes. These have produced changes in apparatus requiring a different technique in application. Until the year 1928 surface cars, rapid-transit cars, and light traction locomotives were propelled by axle-mounted motors driving through single-reduction gears. At that time the lines of traction motors ranged from 25 to 250 horsepower, and the work of application consisted largely of the motor and gear ratio selection to meet the particular service requirements. For this it was usually necessary to calculate the service performance of the motor, chosen on the basis of the engineer's judgment. Motors were self-ventilated and while attention had to be paid to commutating requirements under the most severe conditions of operation and to short-time overloads, the ability to operate within the motor's continuous rating generally insured satisfactory all-around performance. The steady decrease in the cost of energy and increase in car operators' wages had reduced energy consumption to a secondary position instead of one of prime importance which it had occupied 25 years before.

Street Cars

Today street-car and trolley-coach motors are of the light-weight high-speed highly ventilated type. Short-time overloads and accelerating currents must be given more detailed examination. Also standardization of vehicles and equipments has progressed. Practically all city street cars purchased are of the Presidents' Conference Committee or similar type utilizing the same electrical equipment. This was the outgrowth of several years' study. All cars are of nearly the same weight and use the same gear ratio and wheel diameter. A study of operating conditions throughout the country was made and the electrical equipment was then designed to meet the maximum safe speed, balancing speed, and acceleration and electric braking rates specified by the committee and to have adequate capacity for the most severe service likely to be encountered. With such standardization, applications to specific cities obviously involve little additional work.

Trolley Coaches

Trolley coaches came into prominence in 1928. Two sizes are in common use: 30- to 33-passenger and 38- to 44-passenger capacity. The 30-passenger coach is propelled by one 65-horsepower series motor and the 40-passenger coach by two such motors, one 125-horsepower series motor, or one 140-horsepower compound motor. The rear axle of the 30-passenger coach generally has worm drive with 10.25:1 gear reduction. The rear axle of the 40-passenger two-motor coach is generally a double-bowl worm-drive axle or a single-bowl double-reduction axle with a gear ratio of about 9.25:1, depending on the axle manufacturer. The single-motor 40-passenger trolley coaches all have double-reduction axles with gear ratios of approximately 9.25, 10.5, and 11.5 available. Also, the single motor may be used with or without dynamic braking and with different degrees of field shunting. The equipment best suited for a specific application can be determined by economic analysis, comparing the total fixed charges and operating expenses of the various alternatives. Performance calculations are required for this comparison.

While trolley coaches are not standardized to the same degree as street cars, the weights for the same capacity do not differ widely. Hence, when a motor is designed for trolley-coach service, definite effort is made to cover the probable field of application and generally only one capacity of motor is available. Evidently much progress toward standardization has been made.

Performance Calculation

Generalizations regarding the performance of traction motors are frequently misleading. It is safe to say that increased weight of the vehicle always increases energy consumption and increased duration of stop always decreases schedule speed, all other factors remaining unchanged. But the change of any one factor may automatically change some other factor. For instance, if the weight is changed, with a given set of conditions, either the speed margin or the schedule speed must be changed. Both cannot remain the same. Also it is incorrect to assume that changes of the character discussed will always result in the same percentage change, because while the same trend exists the amount of the change is dependent on the characteristics of the particular motor and other conditions.

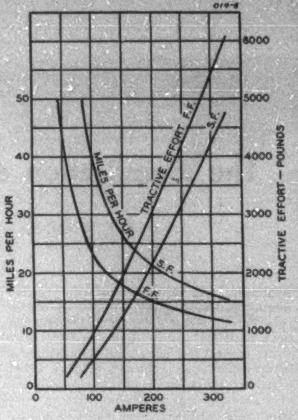

Figure 8. Trolley-coach motor B

Gear ratio, 10.61:1; wheel diameter, 40 inches; volts, 550

Because the trolley coach retains some latitude in the selection of electrical equipment and gear ratio, it is selected to illustrate the method of application. The following basic conditions apply.

The coach weight with average passenger load is 23,000 pounds. The motor has a one-hour rating of 125 horsepower. The gear ratio is 10.61:1 (as extensively used). The effective rolling diameter of the tires is 40 inches. The average voltage is 550, which is typical. Train resistance increases as the speed of the vehicle increases but it varies so widely

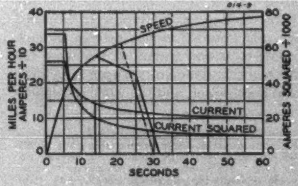

Figure 9. Trolley-coach performance curves

Motor *B*; average voltage, 550; gear ratio, 10.61:1; normal acceleration and braking

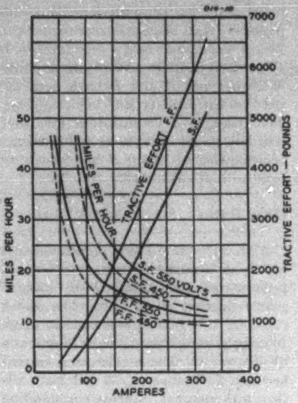

Figure 10. Trolley-coach motor B

Gear ratio, 11.42:1; wheel diameter, 40 inches; volts, 550

with type and condition of pavement that a constant value of 40 pounds per ton is used during motoring. This is amply high for the speeds normally reached. During coasting, the vehicle supplies the no-load losses of the axle and motor. The coasting resistance is thereby increased and a constant value of 47 pounds per ton is used. An average accelerating and braking rate of 3.5 miles per hour per second is used and is as high as can be employed consistently. The minimum time in which the equipment can travel a certain distance under these conditions is increased by a "speed margin" of five per cent (to allow for unavoidable interferences) and schedule speed, motor heating (root-mean-square current) and energy consumption are calculated on that basis.

Figure 1 shows the performance curve of motor *A* on full field and with two percentages of field shunting. The relatively small amount of shunting is designated F.S.-1 and the large amount F.S.-2. By using the motor characteristic, figure 1, and the accepted methods of calculation, the speed-time, current-time, and current squared-time curves are derived and plotted. Starting tractive effort is 4,490 pounds. Accelerating current is 346 amperes. The full-field motor curve is reached at 17.2 miles per hour and the S.F.-1 curve at 18.4 miles per hour. Five different runs between 0.076 mile and 0.369 mile are shown in figure 2.

The one-sixth-mile run may be taken as typical of average trolley-coach service. The required distance without coast is obtained in 29.1 seconds. Adding five per cent speed margin for the typical run with coast gives a running time of 30.56 seconds. The average duration of stop is taken as 7 seconds. Therefore, the total time for this run is 37.56 seconds and the schedule speed is 16.0 miles per hour. The heating current for the total time is 161 amperes which is within the capacity of the motor. The energy consumption is found to be 3.15 kilowatt-hours per coach mile at 550 volts.

The calculated coach performance for the range of runs indicated is shown in figure 3, plotted with stops per mile as abscissas. The decrease in schedule speed and the increases in energy consumption and heating current as the frequency of stops increases are evident. For example, an increase in stops per mile from six to ten decreases schedule speed 23 per cent, increases energy consumption 33 per cent, and heating current 7 per cent.

Field Shunting

The characteristic curve of motor *A*, figure 1, shows by curves F.S.-2 the performance of the motor with fields shunted much more than for F.S.-1. Equipments embodying this characteristic are operating in two cities where they have proved to be very popular with both operators and the public. Their principal advantage lies in maintaining a high rate of acceleration up to high coach speeds and thus enabling the trolley coach to hold a position of superiority where traffic moves unusually rapidly. On the other hand, equipments having the characteristics shown by F.S.-1 are in service in many cities and their performance on the street is entirely successful.

Figure 4 shows the calculated performance with F.S.-2. The full-field accelerating current is the same as for figure 2 but the shunted-field curve is reached at a speed of 25.6 miles per hour instead of 18.4 miles per hour as with F.S.-1. A speed of 30 miles per hour is reached in 10.2 seconds instead of 15.77 seconds. The resulting performance compares with that for F.S.-1 as follows:

Stops Per Mile		Schedule Speed (Miles Per Hour)	Energy Consumption (Kilowatt-Hours Per Coach Mile)	RMS Amperes
2	F.S.-1	24.6	1.84	136
	F.S.-2	28.8	2.21	175
6	F.S.-1	16.0	3.15	161
	F.S.-2	16.7	3.47	186
10	F.S.-1	12.3	4.19	172
	F.S.-2	12.5	4.25	181

Attention is called to the fact that the increased speed of the motor affects schedule speed, energy consumption, and root-mean-square amperes most in the infrequent-stop service and least in the frequent-stop service. The reason for this is the greater amount of operation on the shunted field curve as length of run increases.

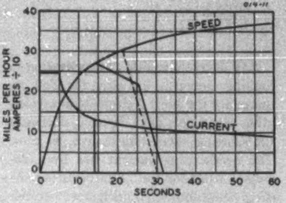

Figure 11. Average voltage, 550; normal acceleration and braking

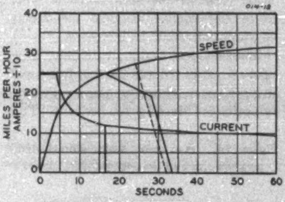

Figure 12. Average voltage, 450; normal acceleration and braking

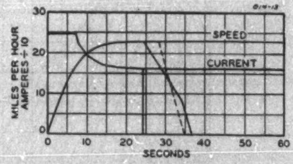

Figure 13. Average voltage, 550; normal acceleration and braking; up five per cent grade

Figures 11–13. Trolley-coach performance curves

Motor *B*; gear ratio, 11.42:1

Acceleration and Braking

Changes in rates of acceleration and braking affect performance. Taking exactly the same conditions as for figure 2, except rate of acceleration and braking, the performance on a one-sixth-mile run has been calculated for the following combinations:

	Rate of Acceleration (Miles Per Hour Per Second)	Rate of Braking (Miles Per Hour Per Second)
Figure 5	2.5	3.5
Figure 6	3.5	2.5
Figure 7	2.5	2.5

Any decrease in rate of acceleration or braking obviously increases the time required for the run. A decrease in accelerating rate alone, as in figure 5, decreases the schedule speed almost five per cent. The accelerating current has been decreased from 346 to 274 amperes but the energy consumption is unchanged because the duration of constant current has been increased. If, instead of maintaining the same speed margin, an attempt were made to make the same schedule speed as in the original example the energy consumption would be increased.

A decrease in braking rate only, as in figure 6, again reduces the schedule speed five per cent. However, the energy consumption is reduced seven per cent. This results from retaining the economically high rate of acceleration and the covering of a greater portion of the distance during coasting and braking when power is not applied to the motors.

When both accelerating and braking rates are reduced as in figure 7, the schedule speed is reduced almost nine per cent and energy consumption is reduced only five per cent.

Slow-Speed Motors

The foregoing comparisons have been with one specific motor. The effect of using a motor with different characteristics, motor *B* of figure 8, will be considered now. This motor has a much slower full-field speed curve than motor *A* and a steep-shunted field curve. In the balancing-speed range the speeds are the same. The effect of the slower full-field curve is to increase the tractive effort per ampere. As a result the starting current is only 260 amperes, or 25 per cent less than the 346 amperes starting current of motor *A*. Figure 9 shows the curves for a one-sixth-mile run.

The schedule speed is 15.64 miles per hour; only 2.3 per cent less than with motor *A*. But heating current is reduced 20 per cent and energy consumption is 17 per cent less. In several cities, motors of both types *A* and *B* have been applied on the same type of vehicle. They have been able to maintain the same schedule speeds and the saving in energy consumption of motor *B* has been very close to that calculated.

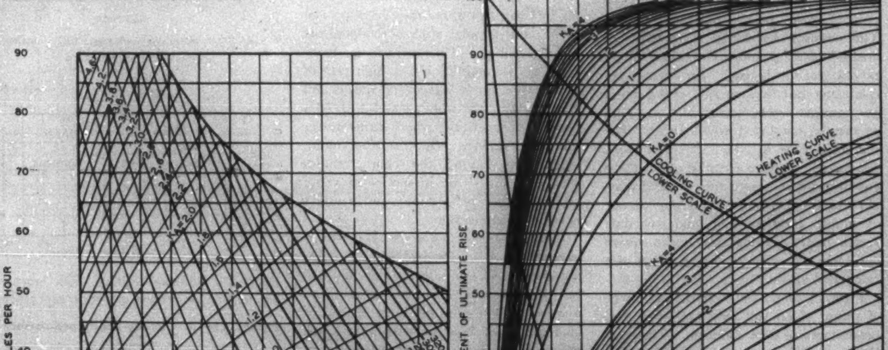
Gear Ratio

With less severe speed requirements it is possible to secure even more economical performance with motor *B* by using a gear reduction of 11.42:1. The motor curve for this gearing is shown by figure 10 and the curves for a one-sixth-mile run by figure 11. The accelerating current becomes 247 amperes, 29 per cent less than with motor *A*. Energy consumption is 20 per cent less but schedule speed is reduced only 3 per cent.

Voltage

Figure 12 shows the effect if the average voltage at the motor is reduced from

Figure 14. A-c series motor ultimate-temperature-rise and time-temperature curves



550 to 450 volts, all other conditions being the same as in figure 11. The schedule speed is reduced almost 5 per cent and energy consumption at the coach is reduced 15 per cent. However, low voltage is usually the result of drop in the distribution system, hence it is necessary to compute the energy delivered by the substation to obtain a true comparison. At 600 volts the values become 2.75 and 2.86 kilowatt-hours per coach mile for the conditions of figures 11 and 12 respectively. The reduction in energy at the car due to slower schedule is more than offset by the energy lost in distribution. Also in any particular service a definite schedule speed must be maintained. Low voltage reduces the amount of coasting and increases the energy consumption at the substation even more than calculated above on the basis of a fixed speed margin.

Grades

Few cities are entirely level. Obviously grades increase running time and energy consumption. When the profile of a line is rolling with its two ends at approximately the same elevation, it is customary to calculate performance on the basis of an equivalent grade resistance. The percentage of equivalent grade is calculated by adding all the rises in feet in a round trip, multiplying by 100, and dividing by twice the round-trip distance in feet.

Where there is a long grade in one direction and a material difference in elevation of the ends of the line it is necessary to calculate both an up-grade run and a down-grade run. Where there are short down grades at various points in a long continuous up grade it is customary to calculate the average percentage grade by adding the rises in feet, subtracting half the sum of the drops, multiplying by 100, and dividing by the length in feet. This formula, as well as that for equivalent grade, is based on the assumption that half of the potential energy in the vehicle at the top of any rise is recovered in useful work in descending the grade and that half is dissipated in the brakes.

On the usual hilly route the profile must be analyzed and divided into various equivalent-grade, up-grade, and down-grade sections. Separate calculations of performance are made for each section and the results combined on the basis of the lengths of the sections. In steam-railroad electrification and rapid-transit work, where the stopping points are definitely known continuous speed-time curves are frequently calculated and the effect of each condition of grade, curve, and speed restriction is taken into account. This process is rather laborious and is used only when the service cannot be represented properly by typical runs.

Figure 13 shows the performance of the same equipment as figure 11 under the same conditions except on a five per cent up grade and with accelerating current held at the same value as on the level. The accelerating rate, therefore, is reduced by the grade resistance of 100 pounds per ton to 2.5 miles per hour per second. Schedule speed is 12 per cent less but energy consumption is increased 75 per cent from 2.52 to 4.40 kilowatt-hours per coach mile.

Rapid Transit

In general, rapid-transit motor application follows the practice used for surface vehicles. In rapid transit, high-speed spring-supported motors with separate gear units have not yet been accepted generally, largely because rapid-transit equipment has always been applied on a very conservative basis. The reasons for this conservatism are (*a*) the seriousness of any failure which may cause a road delay in subways or on elevated structures, (*b*) the large number of cars usually involved in any extension of service, and (*c*) the requirement that new equipment must operate in train with existing equipment. However, in spite of these conditions there is a definite trend toward the use of lighter-weight higher-speed equipment.

Locomotives

The application of motors on locomotives differs from the application on cars or trolley coaches in some respects. The latter vehicles are seldom, if ever, subjected to runs of long duration with the motor tractive effort close to the slipping point of the wheels. Locomotives frequently start and pull trains for long distances under such conditions. Therefore, the locomotive motor must be able to commutate successfully the current required with good, sanded rail. Effort is made to apply electric-locomotive equipment so that the motors in the specified service will not be damaged by any conditions within the limits of adhesion between wheel and rail.

Heavy traction locomotives may run without stops for distances of 50 miles or more over a varied profile. The application of a-c series motors, used principally on such locomotives on electrified railroads, presents problems different from those encountered on d-c motors. The factors which produce heating of the motors are different. The heating of a d-c motor depends almost entirely on the current and ventilation. In addition, the heating on an a-c motor is greatly affected by speed; that is, the current rating increases with reduction in speed. As a result, motor heating depends on horsepower output rather than on current. Consequently, some method other than the calculation of root-mean-square current must be used to determine the heating of a-c series motors.

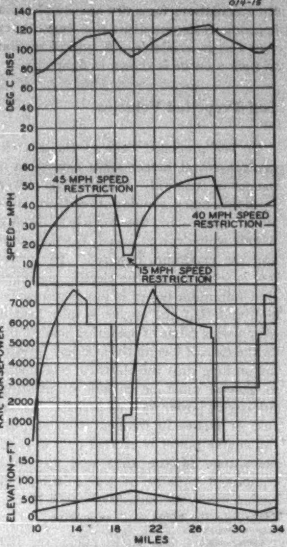


Figure 15. A-c locomotive. Profile, horsepower, speed, and temperature curves

A series of heating and cooling curves for the a-c motor over its entire operating range is determined by test. For each section of the profile the tractive effort and speed are calculated and, from the curves at the left of figure 14, the corresponding values of K_A and ultimate temperature rise are read. The number of minutes for the section is calculated from speed and distance. For this number of minutes the per cent of ultimate rise for the value of K_A is read from the curves at the right of figure 14. This percentage converted into degrees gives the temperature rise in the section. The cooling curve shows the per cent of initial temperature at the end of various durations of no-load operation. When the calculations for a run are completed a continuous temperature-rise curve over that run is available. A typical section of such a curve is shown in figure 15.

Self-Propelled Vehicles

On self-propelled vehicles the electric generator and motor serve simply as a means of smoothly transmitting power from the engine, running at relatively constant speed, to the vehicle's driving wheels which run at speeds between zero and the maximum required. The problem is so to design the electric machines that minimum power is lost in transmission and that the engine is fully loaded over a wide range of operating conditions. In the case of locomotives or cars operating on long runs the electrical equipment in general must be capable of utilizing full engine power for long periods. In the case of busses in frequent stop service, full engine power is exerted only a small percentage of the time and electrical equipment capable of transmitting full engine power continuously would be uneconomically large and expensive.

Gear ratio has little effect on the schedule speed of a self-propelled bus with electric transmission in city service because the input to the electrical equipment is fixed. Therefore, with a specific engine output the tractive effort at any given vehicle speed within the normal operating range is the same regardless of gear ratio, except for the difference in efficiency resulting from different values of current and voltage. The greater the gear reduction with a specific equipment, the greater is the tractive effort at starting, but the lower is the vehicle speed at which the engine is not fully loaded by the generator and "runs against" the governor. Greater gear reductions result in lower current demand and hence lower temperature rise of electrical equipment.

Summary

The basic methods of calculating the service performance of traction motors have proved to be correct throughout years of application. In some installations, at first glance, results in service seem to contradict theoretical calculations. Careful analysis of such cases discloses that the service conditions or methods of operation differ from the basis of calculations. It has been seen that the calculations themselves are simple. To determine the correct basis requires experience and judgment.

To secure maximum economy of operation, the total operating costs must be studied for each application. Higher schedule speeds tend to reduce expense of vehicle operators but increase power costs. For each particular service it must be determined whether increased schedule speed will actually reduce the number of vehicles in service or merely increase wasted time at the ends of the route. On the other hand, it must be borne in mind that high schedule speeds have merchandising value and usually attract additional patronage.

The greatest power economy in city service is obtained by providing motors with the slowest practicable full-field speed and with a shunted-field speed which can meet the requirements of schedules with a speed margin of some five to ten per cent. The highest accelerating and braking rates practicable should be maintained. Vehicles and equipment of the lightest weight consistent with reliable operation and low maintenance should be employed.

In the future a greater degree of standardization may be expected. The continued use of electrical apparatus in transportation is dependent on obtaining the maximum economy both in first cost and operating cost. According to most recent data 8,000,000,000 kilowatt-hours are consumed annually by the electric railways. All electrical engineers should be interested in retaining and increasing this load for the electrical industry.

A New Postgraduate Course in Industry in High-Frequency Engineering

A. R. STEVENSON, JR.
FELLOW AIEE

SIMON RAMO
ASSOCIATE AIEE

THOSE FIELDS of engineering which utilize high-frequency electric currents and electronic devices have long ago graduated from the trial and error stage. The empirical experimenter who is ingenious and observant will always be useful, especially in some new and fruitful phase of the art not yet well understood. However, reliance has for many years been placed upon the ability of the engineer to design analytically upon a sound basis in the underlying theory and analytical tools are recognized as valuable aids and guides in laboratory work.

The newer fields of application in radio have made the engineer's need for a firm foundation in theory constantly more essential. Thus, the complication in both number and operation of the components of a television system is such that the ability to predesign results in untold savings. The problems of short waves have made clear to the engineer that many concepts in electricity he had regarded as basic are narrow in scope, limited to comparatively low frequencies, and inadequate if not altogether erroneous when applied to ultrahigh frequencies.

A major recent development in radio is a system combining frequency modulation with limiters. This outstanding improvement was due to a man who possessed intuition, vision, and courage. He is also a fine analyst in the broad sense of understanding exceptionally clearly what goes on in radio circuits. Success would not have been attained without the intuitive invention but it is doubtful if intuition alone could have solved the problem if the inventor had not had a very clear idea of the theory involved. Of course, after the whole problem had been solved technically, great vision and courage and determination were necessary to bring it to its present state of acceptance.

Even those workers who possess the highly inventive type of mind and are able to find new ideas with only a hazy notion of the theory behind their experiments can have their programs radically accelerated by the assistance of fellow workers who can correlate experiment with sound theory.

To push forward the understanding of high-frequency theory, and provide a solid foundation for good design and

Paper 40-75, recommended by the AIEE committee on education and the subcommittee on electronics, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 22, 1939; made available for preprinting January 5, 1940; released for final publication February 29, 1940.

A. R. Stevenson, Jr., is assistant to vice-president in charge of engineering and Simon Ramo is electrical engineer, General Electric Company, Schenectady, N. Y.

development requires that the engineer possess: (1) the analytical tools; (2) the ability to apply these tools to the solution of practical engineering problems. The latter characteristic includes more than simply the ability to substitute into a formula; it involves also the ability to extract out of a practical situation the problems whose solutions have bearing on the ultimate answers, the judgment to introduce the usually necessary approximations, and finally the important ability to express the results in an easily understandable and useful form.

Need for Course in Industry

Men rarely come to industry direct from college with the amount of training in the difficult radio field that is required for the possession of both of the foregoing characteristics. This is not stated in the nature of a criticism of college curricula. At least as far as undergraduate work is concerned, it is undoubtedly best to give basic and general training to engineers, leaving the study of more specialized branches of engineering to postgraduate work as is being done in many colleges.

Among the subjects of special interest to high-frequency workers but for which there is little time in an ordinary four-year course (and in many five-year courses), is the study of Maxwell's field equations. Unless time is devoted to a study of this theory in postgraduate work, even a phenomenon so fundamental to radio engineering as the radiation of energy by electromagnetic waves is seldom understood. Displacement current may be somewhat familiar to the student but the consequences of the concept are usually not appreciated until problems concerning it are met and solved. Without a feeling for retardation in electrical phenomena one is usually limited to concepts of inductance and capacitance which are valid only at low frequency. Even aside from retardation effects, it is necessary that the high-frequency engineer possess a broader notion of resistance, inductance, and capacity in which current distribution and proximity effects play a part, so that these circuit concepts are not thought of as necessarily independent of frequency. The ideas under discussion here are not new, but there is a need for more young men who thoroughly understand them.

Because it is necessary to teach circuits in a way that will be useful to students who may ultimately enter either the power or communication fields, circuit equations and concepts are most often introduced to the student as one branch of science he must master, and field theory (if treated at all) as another. When the frequency of the circuit is increased to the point that radiation of energy must be considered, the student without additional training is apt to find his circuit concepts inadequate in explaining the phenomenon. For ordinary circuits, he thinks of Kirchoff's and Ohm's laws; for radiation problems there has been little opportunity to equip him with more than a formula or two whose derivation he may not have seen, still less understood.

Transmission-line theory is usually presented entirely from the "voltage along the line" and "current along the line" standpoint. The notion of the transmission of electrical energy by means of propagating fields is so often passed over, or only mentioned as "an interesting way of looking at transmission," that when confronted with the problem of analyzing the transmission of power down the inside of a single hollow conducting tube "wave guide", the student has no basis for attack. Even if time has been found to treat the field concept in college and the graduate does possess a certain amount of appreciation for it, to set up the electromagnetic field equations and solve them in practical cases requires ordinarily more mathematical ability than the student has had a chance to acquire.

In acquainting the student with the operation of electron tubes, the "machinery" of the electronics or radio engineer, the available college time must be limited to the simpler problems. Thus this theory is usually taught in such a way that when higher frequencies are used and problems arise because of the presence of previously negligible transit-time effects, the student must discard what he thought were the basic concepts underlying amplifier or oscillator action and learn a set of more fundamental ones. For example, he can no longer assume that the number of electrons arriving per second at the anode of a diode is exactly equal at every instant to the number leaving the cathode; nor must he take as fundamental that a negatively biased electrode which collects no electrons does by that token not require any driving power.

Some students with more years of college study or an unusual selection of courses obtain a thorough background in the fundamentals of electricity and magnetism and the mathematical tools necessary to apply the theory. To these cases the examples cited are not applicable. However, it is again rare indeed that these men will have had the exposure to the practical type of problem in which the problems themselves are often difficult to isolate and the theory can be used only after a number of engineering approximations have been made.

In general, it may be said that there are three kinds of ability required in engineering work. Analytical ability, though essential, is not the only one demanded by industry. The highly inventive type of mind that contributes valuable ideas, often without apparent need for theoretical background, is one that is unfortunately too rare. The third type of ability, to follow directions and copy designs, also has its place. It is upon the first two kinds of ability, however, that we must depend for technical advancement.

Now, the ingenious inventor is difficult to recruit, for the colleges (especially in undergraduate years) have little time to detect this ability. The analytical man on the other hand is selected by his college record and examinations and trained with success. Since postgraduate study is essential to supply men for the more difficult phases of high frequency and electronics, and since the combination of analytical and experimental ability is so desirable in this field, it has seemed logical to equip men with analytical tools while actually engaged in practical work in industry. This work allows the man with inventive ability to strengthen it while engaged in experiment or design; against it as a background, the newly learned theory may become at once an active tool.

As John Dewey, the famous philosopher and educator has said:*

> "But there is all the difference in the world whether the acquisition of information is treated as an end in itself, or is made an integral portion of the training of thought. The assumption that information which has been accumulated apart from use in the recognition and solution of a problem may later on be freely employed at will by thought is quite false. The skill at the ready command of intelligence is the skill acquired with the aid of intelligence; the only information which, otherwise than by accident, can be put to logical use is that acquired in the course of thinking. Because their knowledge has been achieved in connection with the needs of specific situations, men of little book-learning are often able to put to effective use every ounce of knowledge they possess; while men of vast erudition are often swamped by the mere bulk of their learning, because memory, rather than thinking, has been operative in obtaining it."

This theory of education agrees with the experience of the General Electric Company.

---

* From his book "How We Think," pages 52 and 53.

Postcollege Training at the General Electric Company

The General Electric Company has had experience in fitting men with the essential qualifications implied above for work in electrical, mechanical, and thermal engineering. The three-year postgraduate course, known as the Advanced Course in Engineering,† has been in operation for about 16 years during which time it has graduated several hundred engineers. In view of the successful operation of the courses in other branches of engineering a new section of the advanced course has been organized to cover electronics and high frequency engineering. Before describing the new course it will be well to summarize briefly the aims and operation of the advanced course in general.

When the advanced course was instituted, the company realized that its achievement thus far had rested in a large measure upon the sound technical foundation laid by the pioneers and that future progress would depend on filling their places with high-caliber men who had the ability to think along fundamental lines, apply their knowledge to the development of improved apparatus, and deal generally with the advanced theoretical aspects of engineering work. It was recognized that such work is essentially mathematical in character and that in order to deal effectively with such problems one must be able to use mathematics as a tool in the application of fundamental laws of physics to the problems of engineering and must have a real appreciation of its significance as an aid in straight thinking.

Engineering graduates from American colleges, however, usually did not have sufficient training along the necessary lines. Most of them had no mathematical training beyond the calculus, and those who had studied differential equations had not learned how to make use of them in the analysis of physical problems. There were coming to the company relatively few engineers who were thoroughly grounded in methods of analysis. The courses in many colleges had become too practical; men were being taught routine rule-of-thumb methods of design, and there was insufficient emphasis on thinking problems through by the use of fundamental principles.

The experience of the founders of the course, R. E. Doherty and A. R. Stevenson, Jr., and of those with whom they were associated indicated very definitely that in order to be effective the course should have two major objects. These objects were to train men:

1. To apply the fundamental principles of engineering to the solution of their problems.
2. To present the results of their work clearly and concisely, whether in written form or orally, so that others might easily understand and use these results.

In the 16 years since its founding these objectives of the course have been adhered to.

The first year, or *A* class, is common to all sections of the course and is made up of 30 to 40 men of the testing department who have been with the company only a short time. Entrance is competitive and selection is made from among the applicants on the basis of an examination, school records, and personal interview. Personality and ability to co-operate with others are carefully considered, as well as technical ability.

Those selected remain in the testing department and obtain the same experience there as those not taking the course. In addition, they spend a half day a week in class on company time.

The work during the first year consists of a study of the application of the fundamentals of engineering to the solution of problems involving mechanics, thermodynamics, heat transfer, electricity, and magnetism. Throughout the three years of the course, as far as possible the problems selected are ones which have actually arisen in the engineering departments of the company. In many cases unsolved problems have been assigned, and the classes have thus been given the chance to be of assistance in useful engineering work. These problems differ from most textbook problems in that the students are expected to select from a group of facts those which are necessary for the solution. Another important aspect is that usually it is necessary for the students to make a number of simplifying assumptions in order to bring the problem within the range of practical mathematics. About 15 to 20 hours a week are spent at home by the students in solving and writing up their problems.

Lecture Material in the High-Frequency Section

A few of the 12 or 15 men selected each year from the *A* class for the upper classes are given the final two years of that part of the course dealing with electronics and high frequency. They leave the testing department and are taken directly on the payroll of the advanced course. While on this payroll the men continue to spend at least a half day a week in class on company time. The class work during the second and third year is illustrated by the accompanying chart giving briefly the work of the first year, and in more detail, the lectures of the second and third years.

This chart is intended to show how the mathematical, physical, and design material is developed simultaneously so that uppermost in the student's mind is the regard for the analytical processes as useful tools when properly applied in the solution of engineering problems. The subjects given in the table are intended to be merely illustrative and will change from year to year, although the fundamental nature of the lecture material is preserved. The material is adjusted to fit the needs of the company, the problems which arise, and the previous background of the students such as the *A* class. The technical lectures are given by a great many men from many different departments. In this way, the subjects are presented from many different points of view and there is little danger of the course becoming "inbred".

Problem Assignments in High-Frequency Section

The greatest part of the value of the course is obtained by the student in solving the weekly problems. Therefore, their variety and difficulty are a measure of the engineering ability that is both required and developed. For the purposes of discussion the types of problems assigned in the final two years of the course may be divided into several classes, although, with the exception of the first group discussed below, the problems will usually possess characteristics of two or more of the classes to be described.

The first class of problem is the academic type—given certain facts, to deduce certain relations, or prove other facts. This type of problem is one the student is used to solving from his college career. He finds the problem definite and knows that the answer can be found. Problems of this sort are assigned only occasionally as an exercise when a difficult and new concept is introduced; less than ten per cent of the assigned problems fall into this class.

A favorite type of problem, because of its frequent occurrence in practice and because it leads the student to fundamental thinking, is one that may be described as follows: An engineering design is to be attempted along conventional lines which are outlined to the student;

Problems Encountered in Design	Theoretical Bases	Mathematical Tools
First year common to all sections		
	Mechanics	Differential equations
		Determinants
		Simultaneous linear equations
		Superposition
	Electricity and magnetism	Vector analysis
	Introduction to field theory	
	Elasticity	
	Waves and resonance	Fourier analysis
	Thermodynamics	Dimensional analysis
	Fluid flow	Functions of a complex variable
	Heat flow	
	Radiation	Operational methods
		Fourier integral
		Numerical integration
Second and third years in high-frequency section		
	Vibrating systems	Hamilton's principle and principle of least action
	Approximate methods for calculating resonant frequencies	LaGrange's equations
		Normal co-ordinates
	Hydrodynamics of sound	Review of vector analysis
	Equations of sound waves	Velocity potentials
	Reflection, absorption, attenuation, interference of waves	Solutions of wave equation Generalized curvilinear co-ordinates
	Radiation from various sound sources	Bessel functions
		Spherical harmonics
Horns Loud speakers	Physiological and psychological considerations in sound	
Microphones Sound measurement	Generalization of experimental laws of electricity and magnetism	
	Displacement current	
	Maxwell's equations	Scalar electric and vector magnetic potentials
	Static fields	Solutions of Laplace's and Poisson's equations
Electrostatic shields		Three-dimension flux plotting
	Varying fields in free space	
	Poynting's vector	Retarded potentials
Antennas	Electromagnetic radiation	Hertzian potential
	Electric waves in free space	
	Electric waves in ionized space	
	Electric waves over imperfect-conducting earth	
	Propagation characteristics of long and short waves	
	High-frequency resistance, inductance, and capacitance	
	Waves in and near conductors, guided waves	Solutions of "heat" or skin-effect equation
High-frequency shields	Maxwell's moving images	
Electrical measurements	Introduction to modern physics (radiation, spectra, thermionic emission, photoelectric effect, etc.)	
	Motion of electrons in electromagnetic fields	
Vacuum tubes	Space-charge theory, static and transit-time effects	
	Kinetic theory	
Gas-filled tubes	Conduction through gases	
Rectifiers	Noises in tubes	
	Coupled-circuit theory	
Amplifiers	Reactance theorems	
Feed-back circuits	Circuit theorems	
Oscillators	Four-terminal network theory	
	Introduction to synthesis methods	
	Conventional transmission line theory	
	Characteristics of amplitude, frequency, and phase-modulated waves	Series expansions with Bessel and other functions
Modulators and demodulators	Nonlinear circuits	
Radio transmitters	Distortion in tubes	
Radio receivers		
Applied optics	Geometrical optics	
	Physical optics	
Television devices	Electron optics	

however, because of certain unusual requirements it is feared that the usual type of design may not be satisfactory. For example, a connecting link is to be designed to operate between the antenna of a transmitter and the transmission line feeding it, and the student is acquainted with the usual type of design. In this case, however, the band width of frequencies to be passed is many times that which has ever been attempted with the common design. Should the design be altered or is it nevertheless satisfactory? Can an improved design more applicable to the wide band width be suggested? To deal with a problem of this type the student must ask such questions as: What constitutes a satisfactory connecting link? How does band width enter to determine the requirements of each part of the whole system and their matching? It would have been much easier for the student, had the problem been broken up into the finding of a frequency characteristic for each part of the system—a series of ordinary circuit or transmission-line analysis problems. Then, the student could have been given a series of rules determined by experienced designers by which he could ascertain whether the frequency characteristics indicate satisfactory or unsatisfactory design. But it is in the study of the bases for these rules that the student derives the training that will enable him to make original analyses in the future.

Many valuable problems come from the analyses of new inventions. Often an idea is suggested by analogy with a device in another branch of science or by certain physical considerations, and an analysis is required to determine whether the new idea is a workable one. In this case the student does not know beforehand whether the problem will require a long analytical study with many approximations, or whether the simple application of such tools as the conservation of energy and momentum or dimensional analysis may yield the necessary conclusion. One thing he is often certain of, however, is that the problem has not been solved before.

> **"When pupils get the notion that any field of study has been definitely surveyed, that knowledge about it is exhaustive and final, they may continue docile pupils, but they cease to be students."***

The largest group of problems are those in which an effect or characteristic is known to be present and the problem is that of obtaining quantitative data. These differ from the usual college problem in that in the first place many of them have never been solved before. The student does not have the assurance that by proper application of the material heard in the lecture the week before he is certain to obtain the result. The problem may not be exactly soluble. Almost always a number of approximations requiring a series of preliminary estimates have to be made. The student must decide whether to use a simple technique with additional computations intended to better the accuracy, or to approximate the problem by an exactly soluble mathematical counterpart for which a precise and elegant solution may be made.

Rotating Assignments

As was pointed out in the introduction, it is essential that the engineer (particularly in the high-frequency field) possess a balance in analytical and experimental ability, for one augments and enhances the other. To give this balance, during the second and third years of the course, the students are placed on assignment in various engineering departments of the company. Here they do regular engineering work varying from practice in standard design and manufacturing to research in the newest fields of radio. A good insight into the workings of a department is obtained during the assignment which may last for three or four months. (This period allows time for from six to eight assignments before completion of the course.)

---

* From "How We Think" by John Dewey, pages 197 and 198.

Some of the assignments that the men in the high frequency section may have are as follows:

1. Design of radio and television transmitters and receivers.
2. Design of vacuum tubes.
3. Advanced development problems in radio and television.
4. Design and development of industrial control devices.
5. Design and development of gas-discharge devices of the power type.
6. Mathematical studies in the consulting departments.
7. Research in gas discharges, high-vacuum electronics, dielectrics, vibrations.
8. Research in electrical measurements.
9. District-office engineering, to obtain the customer's viewpoint.
10. Manufacture of radio receivers and vacuum tubes. A knowledge of factory processes and a real appreciation of the factors affecting cost are of prime interest to the radio engineer.

In these assignments, the men have proved so useful to departments in solving difficult problems and contributing new ideas, that the departments are glad to pay the men's salaries and often there are requests for students to fill assignments that must wait because of the limited number of students available.

Conclusions

Under this program, by the end of three years the men have received a thorough training in the fundamentals underlying electronics and high-frequency engineering. They have to a large degree learned how to use the analytical tools needed to apply the theory. It is comparatively easy for the graduate, when he is assigned to one particular phase of radio or television to go on by himself to master the special theory that applies. He is well acquainted with the problems and equipped to pursue their solution. Moreover he has obtained practical experience doing actual engineering work of varied types in regular departments alongside experienced men.

Discussion

H. W. Bibber (Ohio State University, Columbus): Stevenson and Ramo's paper will stimulate the thought of any teacher of electrical engineering who reads it with the problems of education in our field in the foreground of his mind.

To begin with, how is the student a few years out of college going to have the basic concepts in electricity which we gave him, widened in scope and extended to cover the ultrahigh frequencies which have now come on the scene? Here is a chance for the AIEE to help, by the publication in ELECTRICAL ENGINEERING of educational articles specially written for this purpose.

Next, the authors statements as to what the industrial practice of high-frequency engineering requires is very reassuring to teachers who have been advising students who wished to enter this field, to take graduate work with particular emphasis on mathematics and advanced physics. Only a small proportion of students interested in this field can hope to secure employment with a company that has a training course like the one described in this paper.

The quotation from John Dewey serves to remind college teachers of the necessity of continuing some organized laboratory work at the graduate level, in order that use may be made of principles set forth in lectures or in books, "in the recognition and solution of a problem". It is fortunate that high-frequency phenomena may be studied with laboratory equipment that is not beyond the means of the larger colleges to buy or build from parts. The same cannot be said of the study of power systems or large machinery. Postgraduate study while employed in industry has so many advantages that it is only fair to mention one which college postgraduate instruction possesses. That is the easy availability of laboratory facilities to students to settle immediately minor points that may arise in the solution of a major problem. If a student runs into a question of whether an assumption or simplification is justified during an evening's work on a long problem, he may try it out the next morning with a minimum of red tape in securing permission.

It is true that colleges tend to organize and co-ordinate their instruction with assigned problems in courses in order to give a student in a few months a knowledge of principles which it took earlier pioneers in the field many years to learn from haphazard experience. But they do recognize that at an advanced level it is essential for a student to work on problems of an original character, whether he has already mastered the theory necessary to their solution or not. The master's thesis and the doctor of philosophy dissertation are the academic answer to this necessity. A fair share of a graduate student's time is usually devoted to such work, and the award of an advanced degree is usually based on satisfactory demonstration of ability to think independently.

In speaking of ingenuity, the authors state that the colleges (especially in the undergraduate years) *have little time* to detect this ability, and in many other places throughout the paper there is either direct reference to the lack of time and crowding of the curriculum or inferences to the same effect. To speak of the area I know best, I must agree that the curriculum in the great state universities needs lengthening in time with only minor additions to content. If the pressure on our students could be relieved in part they might be encouraged to show inventiveness in their regular course work, or outside of it. They would have time to make use of shop privileges for constructing devices, privileges that I believe are widely offered but little used.

The extension of the curriculum to five years in the state universities should be just a reduction of the credit units per semester, and not a preliminary year (or two years!) of arts work before coming to engineering.

The authors properly place much stress on analysis as one of the desirable qualities to be sought for and developed in students. The counterpart of this quality they mention as "inventiveness," without stressing an educational point which I believe is important precisely in connection with high-frequency work. It is suggested by the item in their list of "theoretical bases" of course content entitled "Introduction to synthesis methods", which is probably intended to apply to synthesis of networks. Most teachers would agree that synthesis should have a far larger place in the scheme of engineering education than it does. It is certainly the fundamental psychological process involved in designing new equipment. Some training in it seems to come as a reflex from training in analysis, and in the machinery field it is difficult to carry out. Thus it would be impracticable to have each student make and put together the laminations, windings, shaft, and frame of a particular motor that he had designed.

But in the high-frequency field, laboratory work intended to develop synthesis is far more practicable. Electron tubes can be built by students themselves within a wide range of dimensions, and circuits built up from a stock of parts which are luckily not so expensive as to prevent a college laboratory from having enough on hand to supply its graduate students. It seems to me that it is in high-frequency work in colleges that synthesis as an intellectual process in electrical engineering may be taught to the extent that it can be taught at all.

A perusal of this paper serves to emphasize the enviable situation of students who secure employment with a big company that can afford to operate a training course —and has the vision to see its value to its future operations—such as that described. For those recent graduates employed in metropolitan districts, the evening courses at the graduate level recently started by some colleges, such as those in the New York City region, may serve as a partial substitute.

Ernst Weber (Polytechnic Institute of Brooklyn, Brooklyn, N. Y.): As the authors point out properly, the average four-year college program in electrical engineering cannot find time for "fundamental" courses, that is, courses which develop the prerequisite mathematical and physical concepts in a rigorous manner and show their applica-

Table I

Mathematical Tools	Basic Theory	Applications

tion in practical problems. One might perhaps refer to the usual undergraduate program as a first "sightseeing tour" to be followed in the postgraduate programs by real "exploration". In this sense, the outline offered by the authors is an excellent contribution from the point of view of industrial training courses and comes very close to our own graduate program except that we spend more time on the individual phases and use considerably more rigor in keeping with formal academic training. Thus, our program for the advanced degrees comprises essentially the individual courses listed in table I of this discussion and grouped in a manner similar to the authors' listing of topics, though not necessarily implying a definite sequence. The courses required of all students for the master's degree are marked (*M*), and those required additionally of all students for the doctor's degree are marked (*D*). For specialization in the field of power or communication engineering a sufficient choice of selective courses is available, including courses in other fields not listed in table I.

The similarity between the fundamental first year of the General Electric course and our required courses is striking, as is also the parallelism of the two years in the high-frequency section of General Electric and our own elective list for students specializing in communication engineering. This need not surprise one in view of the fact that most of our evening graduate students come from the research and development laboratories of the industrial and manufacturing companies of the metropolitan area of New York and, therefore, represent just as selected a group of interested and progressive young men as are admitted to the General Electric training-course program. In fact, our students usually bring with them a rich store of individual experience which makes teaching an enjoyable and gratifying activity. Again, as the authors point out, the success of such a fundamental program depends primarily upon the spirit in which it is carried on and that in turn has very much to do with the teachers of the courses. The great advantage of an industrial training program is the availability of nationally known experts in the particular subjects of study, but there is no reason why the same should not be true for the advanced courses in a well-organized graduate school. More and more emphasis is now given to the appointment of experts to teaching positions in the graduate divisions and to encouragement of industrial contact of teachers by means of conferences, of summer work, and of subsidized research. This is particularly true for our graduate division to which we also were able to attract eminent part time faculty members from the metropolitan industrial concerns. Thus, the old criticism that school training is dry and impractical can no longer be maintained with respect to a graduate program of the kind indicated above.

E. A. Guillemin (Massachusetts Institute of Technology, Cambridge, Mass.): The basic ideas set forth in the paper by Messrs. Stevenson and Ramo with regard to postgraduate work at the General Electric Company are unquestionably sound. They apply equally well, however, to the undergraduate curriculum where in fact it is essential to instill in the students' minds ideas which, even though they are elementary, are entirely consistent with the fundamental principles of electromagnetic theory to be developed later. It was this thought which motivated the rather comprehensive revision of the basic undergraduate curriculum for the electrical-engineering department of the Massachusetts Institute of Technology begun some nine years ago. The undergraduate work cannot be as comprehensive as the usual undergraduate plus graduate study, of course, but there is no reason why, by proper selection of material and form of presentation, the undergraduate work cannot provide a background which is thoroughly sound with regard to fundamental principles so that these need only to be amplified, and not discarded for lack of soundness, when the student proceeds to build upon them in his graduate study, whether this is done in college or carried on in connection with his practical work in industry. The very fact that the industry finds it necessary to give a graduate course of this nature indicates that the need for doing something of this sort in the undergraduate curricula (and perhaps in some graduate curricula) is not generally recognized.

As a specific example let us consider a semiqualitative discussion of the relation between field theory and circuit theory. One naturally cannot expect a sophomore to fully master the mathematical mechanism necessary for a complete discussion of this rather complex problem. On the other hand, it is entirely possible and appropriate to forewarn the student that the lumped circuit parameters (*R*, *L*, and *C*) as calculated by the ordinary engineering methods are merely approximations which are adequate for the lower-frequency ranges. Qualitative reasons for this can readily be given; it is even possible to derive rough criteria which show when and why the simple methods may be expected to fail. Even if this first presentation is not properly digested by the student, he has at least acquired an open mind on the question and need not suffer disillusionment later on in finding things to be only half true which he had always been led to understand were the whole and unshakable truth.

It is another principle in our scheme of undergraduate instruction that when a conception is sufficiently fundamental, though admittedly difficult to assimilate, a certain percentage can eventually be made to "stick" if brought to the student's attention in small doses at sufficiently frequent intervals. In our opinion it is definitely unsound to maintain that certain so-called "advanced" concepts are inappropriate for undergraduate instruction. A course of action based upon such a premise makes the shock fatal when the time comes to tell the truth.

Here at MIT, after a certain background for the relation between electromagnetic field theory and circuit theory has been laid in the sophomore work, the student is conditioned to a certain degree to receive a more substantial dose in a subject dealing with transmission line theory which is given to the seniors in the communications option. This subject is introduced by an elementary discussion of electromagnetic wave propagation—plane waves in free space, conductors, or semiconductors, surface waves and the accompanying phenomenon of skin effect. The theory of the radiating dipole and its application to antenna problems, which forms the concluding material in this subject, follows also quite logically from the same introductory discussion.

It is fully realized that only a few of the abler students get more than a moderate grasp of the more advanced portions of such a discussion. We have no illusions on this score. But we do feel that attempts of this nature are worth the time and effort. For if some of the men do continue in this field in their graduate work it will then be a third exposure for them and they should be in a position to accomplish something worthwhile, whereas a serious treatment of fundamental electromagnetic theory will still be just a play of symbols to them if it is their first exposure.

There is, of course, a certain amount of good judgment in postponing the presentation of material of a more special nature until the graduate year because of the fact that the average graduate class is a more select group of students from the standpoint both of ability and serious interest. However, it is also possible to inject into the undergraduate teaching procedure the necessary flexibility to make available to the student a variety of opportunities to suit the individual or group interests and abilities. The procedure of sectionalizing according to mental speed, the individual encouragement given the more able students, and the operation of the honors group system are methods which have proved useful toward making possible the differentiation in subject matter and in teaching procedure necessary for effectively carrying out a more ambitious program.

The comprehensive written and oral examinations given the honors group men in place of the ordinary term examinations provide original problems of a comprehensive nature (contributed by practicing engineers) requiring for their solution the initiative and perspective which Messrs. Stevenson and Ramo point out as being essential to the proper training of student engineers.

Finally I would like to state the opinion that graduate courses in the industry excepting those peculiar to a particular industry are fine for those students who cannot afford such study in college, but since this type of work is a side line for the industry it should follow that the college, whose primary responsibility is teaching, can do a better job of it. On the other hand it is clear that efforts of this sort on the part of the industry are bound to have beneficial effects, not only within their own group but also in academic circles because such activity cannot but stimulate thoughts along these lines by men having teaching responsibilities and thus lead them to make more constructive appraisals of their own efforts.

C. Francis Harding (Purdue University, Lafayette, Ind.): Although possibly directed more effectively to the selection of personnel for such an advanced course than to the content thereof, I would like to ask what credit and advancement are available in such a program for those who have secured their master of science or doctor of philosophy degrees in the graduate schools of universities and colleges? Although it has been stated that such courses in industry are not in competition with similar graduate courses in the universities, yet unless advanced students entering industry can capitalize upon such university graduate training the competition does really exist and the time is actually lengthened during which the new employee must remain in training before he is able to carry responsibility.

The five-year courses which are being considered at various universities and the relation of their resultant product to the regular four-year curriculum, plus a year's graduate course in industry, have been presented. The necessity for more time for assimilation of the curriculum and for thesis or other original work on the part of the undergraduate student has been emphasized. It may be of interest to note that Purdue University has just established two new five-year curricula in engineering to meet such needs. Curriculum *B* is identical in content, and in the bachelor of science degree granted, with the present curriculum *A* except that it is spread out over five years. Curriculum *C* contains approximately 24 credit hours of nontechnical subjects with the specification that there shall be included therein a minimum of three extra hours of economics, six hours of history and/or government, and six hours each of advanced mathematics and physics. The remainder of the extra credit hours are expected to include more of the humanities, English literature, and social sciences. The same bachelor of science degree is granted with certificated recognition of the extra work which has been accomplished. The minors of a master of science degree may also be satisfied in such a curriculum if the subjects are selected with proper care and approval.

These curricula should not be considered as replacing, in any sense, the present standard four-year engineering curricula. They are made available as substitutes for those interested in devoting more time to the securing of the bachelor of science degree or for those who wish to secure a broader cultural background for such a degree. They are not expected to decrease the interest in, nor the election of, the requirements for the more rigorous curricula leading to the master of science degree.

R. W. Sorensen (California Institute of Technology, Pasadena): If I were to apply the common critical methods of my occupation to this paper, I would begin by changing the title to the extent of eliminating the word "new", thus having the title read: "A Postgraduate Course in Industry in High-Frequency Engineering". I do this, because I am not acquainted with any other postgraduate course in high-frequency engineering and I would like to give full credit to the authors for their original, efficient, and complete way of laying the proper groundwork or foundation for a particular engineering activity incident to the work being done by the company by which the authors are employed. When many of us were young men just out of college, our training courses with industry were quite different. We took our place in the shop with the workmen and organized our own theoretical classes or seminars, if any.

As a college teacher, I am more than gratified to note the continued introduction of special advanced courses by industry to meet the needs which arise, particularly as these courses are of a type that not only supplements the work done by technical men in college, but continues to develop in these men, in parallel with their supplementary practical work, an interest and a facility in the theoretical and analytical aspects of the work they are doing.

The course under discussion is such that it could well be a regular graduate course given in an engineering college, and therein lies one danger which should be avoided. That is, I think colleges should not give courses of the type described, not because of lack of quality or trend of such courses, but rather because such courses are too specialized for a general course and hence are too specialized for college courses.

In fact, one of the authors of this paper and builders of the course described in the paper is a young man recently out of college who did not have such a course as a part of his college curriculum. Nevertheless, he has been able to plan and teach the course here outlined. He could do this, because he obtained a doctorate degree for the completion of a graduate course in electrical engineering, a considerable part of which comprised advanced courses in physics and mathematics, taught by the ablest of teachers and research men specializing in these subjects, rather than by engineers somewhat versed in mathematics and modern physics. Even as an undergraduate, the college course which the author had, provided some tools for doing work of the type described in this paper. As the use of one tool was mastered by Doctor Ramo other subjects listed as tools in this paper were added, very much in the order named, as his work continued throughout the graduate course.

In fact, about the only contribution which I see can be made to the paper by my discussion is to show that the course described is sound, because it provides the men taking the course with technical ability which will enable them to make analyses which keep pace with the developments that take place in this field in laboratory and shop. Also, it provides for a continuation of theoretical and analytical study by men who have been properly prepared for such work and thus further knits together our whole program of education in college and industry through a co-operative rather than a competitive program.

As long as colleges confine graduate work to equipping men with analytical tools rather than endeavoring to do things which naturally pertain to industry, in the way of developing designers, etc., and do not make graduate courses merely continuations of undergraduate work—just so long will our whole educational program be an efficient, co-operative one between the colleges on one side and industries on the other.

A. R. Stevenson, Jr., and Simon Ramo: It is reassuring to the authors to find their colleagues in the colleges, who are specialists in the field of engineering education, in general agreement as to the advisability of training along broad, fundamental lines in preparation for engineering work in high frequency and electronics.

The question has been raised as to what credit and advancement are available to students with advanced degrees in a program such as we have described. To answer this, it should first be pointed out that there is no "standardization" in the placing and developing of men in the General Electric Company. This applies also to the placing and training of men in our advanced course. Each man is considered as an individual case. We have had some doctors of philosophy whose ability and training were sufficiently removed from that which we try to develop in the course that they were not able to complete the work of the first year. Others have been given only one or two years of the three-year course and some have been given the job of supervising a year of the course which they did not take.

We like to have men with advanced training in our classes both as students and lecturers. We depend upon these men who come to us with new tools learned under skilled professors to add to our course ideas of which we might not otherwise be aware.

It has been stated in discussion that co-operation between industry and the colleges makes for the most efficient educational program. From our standpoint, this statement has already been borne out well by the discussions presented by the teaching profession; many ideas were put forth which will help us to improve our educational system and make the best use of the collegiate training of the student engineer.

Condensation of Mercury in Mercury-Arc Tubes

JOSEPH SLEPIAN
FELLOW AIEE

W. M. BRUBAKER
NONMEMBER AIEE

Synopsis: It is found experimentally that the efficiency of condensation of mercury vapor on cold metal surfaces is quite low. The condensing efficiency of steel surfaces is increased several fold by positive-ion bombardment of the surface. Nickel surfaces condense mercury vapor several times as efficiently as steel. The operation of a high-voltage ignitron rectifier was greatly improved by positive-ion bombardment of the condensing surfaces.

IN mercury-arc power converting tubes, there is a continuous evolution of vapor from the mercury-pool cathode. This vapor is recondensed upon condensing surfaces which are kept cool by water, in larger tubes, and forced or natural circulation of air, in smaller tubes. The vapor density existing in a tube will then depend on the dynamic balance between the evolution at the cathode, and the removal of vapor by condensation at the condensing surfaces. It is well known that the successful operation of mercury-arc tubes is strongly dependent upon the vapor density being kept low, at least in the neighborhood of the anodes. If the temperature of the condensing surfaces is allowed to exceed 60 degrees centigrade, operation usually becomes unsatisfactory due to excessive frequency of arc back.

In estimating the vapor density which might exist in mercury-arc tubes, the authors, and probably also mercury-arc tube engineers generally, had not been seriously concerned about a possible low efficiency for condensation on the condensing surfaces. Elementary mechanical considerations lead them to believe that heavy mercury atoms, striking a surface made up of atoms not heavier than mercury atoms, should lose all their kinetic energy with no recoil, and come to rest on the surface. Thus, all mercury atoms reaching the surface should be condensed, with no direct reflection, and mercury atoms should leave the surface again only as re-evaporation. Because of the low temperature of the condensing surfaces, this re-evaporation is generally negligible.

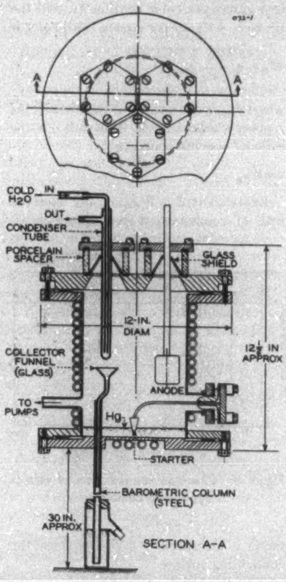

Figure 1. Mercury-condensation chamber

In estimating vapor densities, therefore, the authors never took into account a possible counterflow of molecules from the condensing surfaces, and it seemed that condensing surfaces generally used were sufficient to ensure a low vapor density at the anodes of tubes in operation.

It was a considerable shock, therefore, when Doctor R. C. Mason[1] called their attention to the fact that only for extremely clean condensing surfaces is the direct reflection of mercury atoms negligible, and that slight contamination, quite unavoidable in practical tubes, would reduce the condensing efficiency to very low values. This phenomenon has been known a long time to physicists,[2] but its significance seems not to have been appreciated by engineers.

It seemed desirable then to make a direct study of the efficiency of condensation of mercury on various surfaces under conditions similar to those existing in practical operating mercury-arc steel tanks. Also, it was desired to check the idea that continuous positive-ion bombardment might keep condensing surfaces sufficiently free from contamination that their condensing efficiency might be kept high.

Apparatus

The apparatus in figure 1 was built around an experimental ignitron tank as a foundation. The coils which are soldered to the sides and bottom of the tank were connected so as to form a closed circulating system with a water pump, electric water heater, and a thermostat. Thus, the temperature of the mercury in the bottom of the tank was known to the accuracy of the operation of the thermostat, which was plus or minus one-half degree centigrade. The special top plate, with provisions for three small electrodes was made for this experiment. The three electrodes were insulated from the rest of the apparatus by the porcelain spacers; the bolts which held them in place were insulated from the electrodes by Micarta bushings. Two of the electrodes were of the shape and size of the one shown on the left, while the third was an "anode," as shown on the right. Glass funnels under each of the two similar electrodes conducted the mercury which condensed on to and fell from the condensing tubes to the two barometric columns. Mercury so collected was drained from the barometric columns and weighed at suitable intervals. Readings taken in this manner had no effect on the conditions within the chamber. The third electrode, as shown, was used as an anode when it was desired to run an arc in the chamber, simulating conditions in an ignitron. Tap water was used to cool the condensing tubes. Seasonal fluctuation caused the temperature of the tap water to vary between 10 and 25 degrees centigrade. The vapor pressure of mercury in equilibrium with condensed mercury in this temperature range is low in comparison with that at 60 degrees centigrade, as the pressure doubles for each 10-degree rise in temperature in this range.

Paper 40-72, recommended by the AIEE subcommittee on electronics, and presented at the AIEE winter convention, New York, N. Y., January 22-26, 1940. Manuscript submitted November 6, 1939; made available for preprinting January 2, 1940; released for final publication February 23, 1940.

JOSEPH SLEPIAN is associate director of research of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.; W. M. BRUBAKER is with the same company.

1. For all numbered references, see list at end of paper.

Calculation of Efficiency From Observed Condensation

Besides directly investigating the relative yields of condensed mercury from various surfaces under different conditions, it is desirable to make an estimate of the efficiency, or condensation, coefficient. This coefficient may be defined as the number of molecules condensing divided by the number of molecules striking the surface. If the area under consideration is a condensing surface of extremely poor efficiency, so that there is no appreciable flow, a formula from simple kinetic theory may be used to compute the number of molecules which strike the surface per second. At the other extreme, a surface of 100 per cent condensing efficiency appears to the condensing vapor as a hole into a completely evacuated chamber. In this case, the vapor at the condensing surface is in a state of flow, and its density and temperature are different from that of the vapor at rest far from the surface. We may calculate what this flow will be by using the mathematical theory of the mechanics of continuous fluids, although we must recognize that at the condensing surface this theory fails to be applicable, since the vapor there, with its non-Maxwellian distribution of molecular velocities, cannot be said to have a scalar pressure and temperature as contemplated in fluid mechanical theory. However, this theory should be applicable up to within a few molecular mean free paths from the surface. We may then attempt to modify the simple kinetic-theory formula, by taking into account the flow and the altered density and temperature predicted by the continuous-fluid mechanical theory.

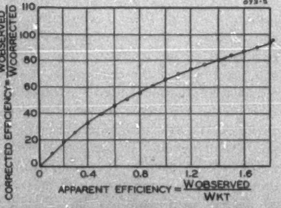

Figure 2. Calculated efficiency as function of observed yield

Kinetic theory gives v the number of molecules crossing from one side to the other side of a unit surface in unit time in a gas in equilibrium as

$$v = {}^1/_4 N\bar{c}$$

where N is the number of molecules per unit volume, and $\bar{c}$ is the mean velocity of thermal motion. The weight in grams of these molecules is

$$W_{KT} = p\sqrt{\frac{M}{2\pi RT}} = 43.7\times 10^{-6} p\sqrt{\frac{M}{T}} \qquad (1)$$

where p is the pressure, dynes per square centimeter, M the molecular weight, T the absolute temperature in degrees Kelvin, R the gas constant in ergs per degree, and the units of area and time are the square centimeter and second.

From the mechanics of continuous fluids the mass of a perfect gas flowing per second across an area of one square centimeter at a point where the density is ρ grams per cubic centimeter, and the pressure p dynes per square centimeter is

$$W_H = \sqrt{\frac{2\gamma}{\gamma-1} p_0\rho_0 \{x^{2} - x^{\gamma+1}\}} \qquad (2)$$

where p_0, ρ_0 are pressure and density at a point where the fluid is at rest, γ is the ratio of specific heats and

$$x = \rho/\rho_0$$

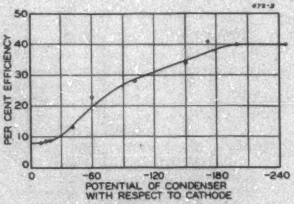

Figure 3. Effect on condensation of voltage applied to condenser

Experimentally, W_{observed}, the observed rate of condensation per square centimeter is measured. Obviously, near the condensing surface

$$W_{\text{obs}} = V\rho = Vx\rho_0 \qquad (3)$$

where V = mean or hydrodynamical velocity of motion of the gas toward the condensing surface. Assume that the molecules of the gas have a Maxwellian distribution of velocities about a set of axes moving toward the surface with the velocity V, although as mentioned before, this cannot be true within a mean free path of the condensing surface. From equations 2 and 3, we calculate V and x. We then return to (1) and modify it to obtain an expression for the number of molecules striking the surface in terms of the pressure and temperature of the vapor in regions unaffected by the condensation, and where it is at rest, taking into account the effect of the hydromechanical motion corresponding to the observed rate of condensation. Equation 1 is derived by integrating

$$\rho\int_0^\infty uf(u)du$$

where $f(u)$ is the Maxwellian distribution function for the velocities in a direction perpendicular to the area. If the body of the gas or vapor is approaching the surface with a velocity V, the distribution function will be $f(u-V)$. As we are interested in knowing how these conditions deviate from those in our first equation, we let

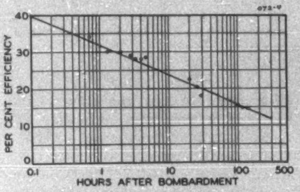

Figure 4. Decrease of condensing efficiency with time after bombardment

$$R = \frac{\int_0^\infty uf(u-V)du}{\int_0^\infty uf(u)du}$$

$$= e^{-\left(\frac{V}{\alpha}\right)^2} + \sqrt{\pi}\frac{V}{\alpha}\left[1 + P\left(\frac{V}{\alpha}\right)\right]$$

where $P(y)$ is the probability integral

$$P(y) = \frac{2}{\sqrt{\pi}}\int_0^y e^{-y^2}dy$$

and α is the most probable molecular velocity. Thus, equation 1 should be multiplied by R to allow for the motion of the vapor toward the condensing surface.

As the gas moves toward the condensing surface, it undergoes an adiabatic expansion. The changes in p and T from the equation of state of a perfect gas are given by

$$x = \frac{\rho}{\rho_0} = \left(\frac{p}{p_0}\right)^{\frac{1}{\gamma}} = \left(\frac{T}{T_0}\right)^{\frac{1}{\gamma-1}}$$

where γ is the ratio of the specific heats which for mercury vapor is 1.66. Hence, equation 1 will need to be modified to allow for this changed density and temperature by multiplying by $x^{\frac{\gamma+1}{2}}$. The value of α in the correcting factor R, is also a function of x.

Combining all of these correcting factors, we obtain for calculated mass of molecules striking a centimeter square of area of condenser per second,

$$W_{\text{corrected}} = W_{kT}x\frac{\gamma+1}{2}R$$

$$= A(M, p_0, T_0, \rho_0, \alpha_0)F(W_{\text{obs}}) \qquad (4)$$

where A is a function of the conditions existing in the vapor at parts unaffected by the presence of the condensing surface.

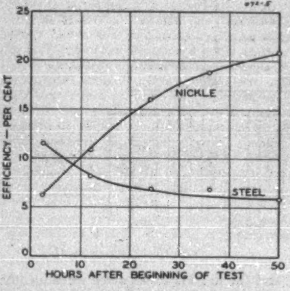

Figure 5. Efficiencies of condensers during a test

The corrected efficiency $W_{\text{observed}} \div W_{\text{corrected}}$, can then be calculated from the apparent efficiency, $W_{\text{observed}}/W_{kT}$. A curve of corrected efficiency is plotted against apparent efficiency in figure 2. The data in this paper are expressed in terms of the corrected efficiencies as taken from figure 2.

Experimental Results

With the temperature of the condensed mercury 60 degrees, and that of the condensing surfaces 10 to 25 degrees centigrade, the efficiency of condensation of mercury vapor on freshly sand-blasted steel electrodes is found to vary between 1.5 per cent and 8 per cent. This variation is attributed to different surface conditions.

Surfaces which have been roughened with coarse alundum cloth and washed in alcohol or benzene give results similar to sand-blasted surfaces, as do freshly machined (rough lathe turned) steel surfaces. We found no treatment of a steel surface, prior to its insertion into the vacuum chamber, which would cause its efficiency of condensation to be higher than that of a sand-blasted surface.

To simulate conditions existing in an ignitron, the third electrode (on the right in figure 1) was used as an anode, and an average current of 15 to 50 amperes was passed through the tube when it was being used as a half-wave rectifier feeding a resistance load from a 220-volt a-c power source. It was found that the yield obtained from the condensing tubes during alternate one-hour periods when a 15-ampere arc was run in the chamber was 20 per cent higher than that observed during the interspersed one-hour periods when no arc was run. This was taken as an indication that the presence of the arc raised the pressure of the mercury vapor in the tube by 20 per cent.

Effect of Negative Voltage Applied to Condensing Surface

The application of a negative potential, with respect to the cathode, to the condensing tube is believed to cause it to be surrounded by a positive-ion sheath during the conducting half cycle. The thickness of the sheath, according to Langmuir's theory of currents to a probe in a plasma, is small in comparison to the diameter of the condensing tube. Positively charged mercury ions then will fall through the sheath and bombard the condensing surface with an energy which is proportional to the potential difference between the arc plasma and the condensing tube. The positive-ion current collected by the condensing tube does not vary as the negative potential of the tube is increased, which is as should be expected if the thickness of the positive-ion sheath remains small, since this current is determined by the random positive-ion current density in the plasma, and all of the positive ions which come to the sheath are drawn to the condensing tube.

The bombardment of the condensing surface by positive ions has a remarkable effect on its efficiency of condensation. The manner in which the efficiency increased as the negative potential was increased is shown in figure 3. These data have been corrected for the increase in mercury-vapor pressure caused by running the arc, as explained earlier. The observed increase in efficiency cannot be explained by the simple collection of positively charged molecules, since the current drawn by the condensing tube and the amount of condensation are of such magnitude that there are of the order of 1,000 mercury atoms collected for each positive charge. Hence, we must conclude that the positive-ion bombardment so alters the condensing surface as to increase its efficiency for the condensation of neutral molecules. The efficiency of the condensing surface as a function of time after the arc is turned off is shown in figure 4. The rate at which the efficiency decreases, as well as the value it reaches in a given time, is a function of the length of the preceding bombarding period; if the bombardment has been for a few hours instead of several days, as it was before the data of figure 4 were taken, the efficiency returns to its initial value of less than ten per cent in less than a day.

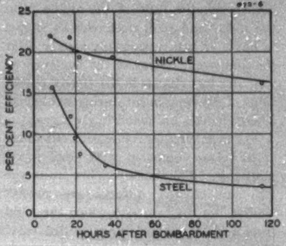

Figure 6. Decay in efficiency after stopping positive-ion bombardment

Condensation on Nickel

The condensation of mercury on a nickel surface was also investigated. One of the steel electrodes shown in figure 1 was replaced by a similar one made of nickel, and in this manner the behavior of the two surfaces was compared under identical conditions. The interesting difference in the rate at which mercury condenses on the two surfaces is shown in figure 5. In this instance, the steel electrode had been bombarded by positive ions before the nickel electrode was placed in the chamber. No arc was run after the insertion of the nickel electrode. The yield from the steel electrode declined as in figure 4, but the yield from the freshly sand-blasted nickel electrode increased during the same interval of time.

When the nickel and steel electrodes are bombarded by positive ions, the maximum yield obtainable from each is similar. After the arc was turned off, the yields from the two electrodes decreased as shown in figure 6.

When two freshly sand-blasted electrodes, one steel and one nickel, were placed in the evacuated chamber and a temperature difference between the mercury pool and the electrodes maintained, the interesting curves of figure 7*a* were obtained. The absolute yields show large fluctuations during the month period, but the ratio of the yields from the nickel and steel electrodes as shown in figure 7*b* was remarkably steady after the first week. Some of the fluctuations were due to a change in the steady conditions of the experiment during weekends. These changes are noted in the figure.

The much greater condensing efficiency of nickel as compared with steel is remarkable. The initial yields from the two sand-blasted surfaces are always similar, but the rate with which the yield from a nickel surface improves did vary. Thus, as shown in figure 5, the improvement was more rapid than in figure 7*a*. Apparently the rate of improvement depends on the time between sand blasting and the setting up of a temperature difference for condensation.

Effect of Electric Excitation of Condensing Surfaces in Operating Rectifiers

Some preliminary tests were made to determine whether improving the condensing efficiency by positive-ion bombardment of condensing surfaces would give any improvement in performance of operating rectifiers. For these tests we used a pair of ignitrons as a full-wave rectifier, feeding into a resistance load at 8,000 volts direct current. During the greater part of the test, the load current was maintained at 25 amperes, and the condensing surfaces were energized on alternate one- or two-day periods, unenergized on the intervening periods. The number and distribution of observed arc backs are shown in figure 8*a*. The arc backs appear to occur at random during both the energized and unenergized periods. The average number of arc backs per hour was 0.862 and 0.08, a reduction of more than ten by the application of potential to the condensing surfaces.

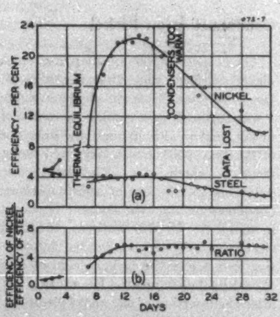

Figure 7. Comparison of nickel and steel condensers over 30 days

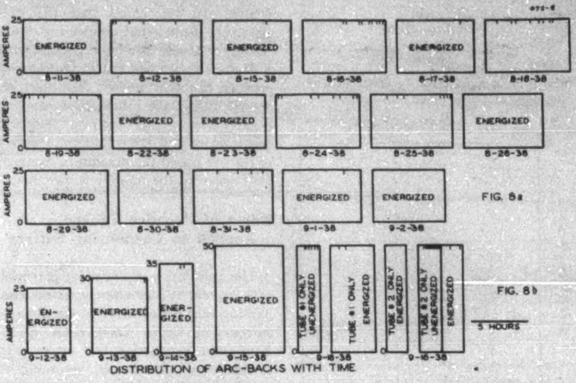

Figure 8. Plot of arc-backs observed with two ignitrons feeding an 8,000-volt 25- to 50-ampere resistance load

Arc-backs indicated in figure 8*a* are for either tube, those in figure 8*b* are for the individual tubes

The first part of the test was concluded by the failure of the mechanical vacuum pump. After the ignitrons had again been treated out, a short test was made at higher currents, to 50 amperes. The data of this test are shown in figure 8*b*. An entire day without a failure was obtained while the condensing surfaces were energized on September 15. The next day the surfaces of one tube at a time were de-energized, and the data for the two tubes are shown separately. Both tubes operated satisfactorily for a while, but the one whose condensing surface was de-energized soon began to fail. Tube 2, when de-energized, ultimately became so bad that it would not carry the load for as long as one minute. When the surface was energized, it failed only twice in the following two hours. This complete failure to carry the greater load of 50 amperes when the surfaces were not energized, and the immediate ability to operate satisfactorily when the surfaces were energized were verified by data similar to that in figure 8*b* several times.

However, when the tubes were being operated at 3,000 volts direct current, and the arc backs occurred infrequently, no definite improvement was obtained by the application of potential to the condensing surfaces. Similar tests on larger ignitrons at 600 volts also failed to show conclusively that arc backs were reduced in number by improved condensation.

Summary and Conclusion

1. Very low condensing efficiencies for mercury usually less than ten per cent were found for water-cooled steel surfaces under conditions simulating those obtaining in practical steel-tank rectifiers.

2. Positive-ion bombardment of condensing surfaces caused a great increase in their condensing efficiency.

3. Nickel surfaces usually showed a condensing efficiency several times as large as for steel surfaces.

4. Positive-ion bombardment of the condensing surfaces of an 8,000-volt d-c 25-ampere single-phase ignitron rectifier greatly improved its operating performance. Similar treatment of a 3,000-volt 200-ampere single-phase ignitron, however, gave no improvement in performance.

Electric Power for Airplanes

W. J. CLARDY
MEMBER AIEE

Synopsis: Electric-power loads are increasing rapidly on airplanes and auxiliary-engine-driven generators offer dependable power sources independent of main engines. Minimum weight for the required capacity is essential in the design of generators, motors, and control. The a-c 110-volt 400-cycle three-phase system has been developed for large airplanes with heavy motor loads. Alternators rating 12.5 kva at 75 per cent power factor and two-pole motors running at 22,500 rpm full-load speed are available. Control apparatus builds up the alternator, establishes accurate voltage regulation, and provides direct current for excitation and battery charging. The 24-volt system is applied on airplanes using d-c power which have relatively light motor loads. Generators rate 5 kw and are designed for speeds ranging from 3,200 to 6,000 rpm to conform to prime-mover requirements. Motors have been built which run at 7,500 rpm. The control effectively regulates the voltage, handles battery charging, and provides for starting the power plant.

Featherweight Electrical Apparatus

An engineer intently watches the speeding motor shaft—so fast that it is just a blur to the eye. The light of the stroboscope is turned on it and the shaft is seen stationary. The surface of the small 22,500-rpm rotor of the six-horsepower motor travels the distance from New York to Chicago in less than four hours. This is one of the impressive electrical developments for airplanes wherein speed goes up and weight comes down. There is an insistent demand to save "pounds" in aircraft electrical equipment and thus increase "pay-load" capacity. Featherweight generators, motors, and control are now available for such applications.

Airplane Electric-Power Problems

The growth of electric-power loads on airplanes coincides with increases in size, speed, and flying range. Aircraft developments have been extensive during the past few years, resulting in substantial boosts in the uses of electrical energy. Small 6- or 12-volt d-c automotive-type generators, either main-engine driven or located in the air stream, have long served as power sources. These low-voltage systems are inadequate for modern airplanes because of low weight efficiency. It is necessary to apply large generators operating at relatively high voltage to assure economic installations. The result has been the development of the auxiliary-engine-driven power plant, trial of the five-kw main-engine-driven generators, and investigation of steam, hydraulic, and exhaust gas turbines as prime movers.

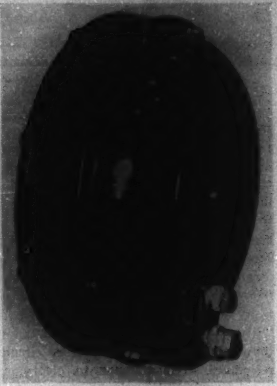

Figure 1. Aircraft alternator

This is a 400-cycle three-phase machine and is rated 12.5 kw, 120 volts at 75 per cent power factor. It weighs close to 100 pounds

The auxiliary-engine-driven generator offers a satisfactory means of power supply, continuously available under all operating conditions, independent of the main engine. Units are designed to secure minimum weight for a specific flight time. This requires consideration of the weight of the fuel, oil, engine, generator, and control as well as the efficiency of the plant. Low fuel and oil consumption, which means high engine efficiency, are pertinent in equalizing the weight of fuel and oil with that of the engine. The generator requires the same consideration. A balance must be reached for generator active parts in comparison with fuel and oil weight for a given flight period.

Motors are being extensively used to perform various functions on airplanes. Light weight is essential and in this case, efficiency, the duty cycle, and ventilation affect design. Here again, efficiency has a bearing on the power used and can be evaluated in terms of fuel and oil weight. However, the duty cycle is a factor since high efficiency becomes progressively more important in terms of fuel and oil weight for momentary, intermittent, and continuous operation. Motor weight will go up with decreased ventilation which makes it desirable to limit the use of explosion-proof and enclosed types.

110-Volt A-C System

The 110-volt 400-cycle three-phase a-c system is applicable to large aircraft. Alternators have been built and tested which are rated 12.5 kva at 120 volts and 75 per cent power factor, and weigh practically 100 pounds. The machines operate at 3,430 rpm, a speed which is fixed by the prime mover. Rotors have 14 poles and are mounted on engine-shaft extensions to eliminate bearings. The same shaft extension carries a propeller-type fan which provides additional flywheel effect, cools the engine, and ventilates the alternator. Stators are attached directly to engines.

Alternator efficiency is 92 per cent, a figure selected after an analysis of the weight of the complete power plant plus fuel and oil. Above 92 per cent efficiency,

the increase in alternator active parts balances the fuel and oil weight reduction for a 40-hour flight. Overload capacity is determined by sudden load changes, such as may occur with the starting of large induction motors. This is particularly true if the lights and continuous-running motors are operating and momentary starting loads are applied. This condition may reduce voltage too much and consequently alternators are designed for high current overload capacities at low power factors.

Lightweight high-speed induction motors are well suited for 400-cycle three-phase operation. A wide speed range is obtainable by varying the number of poles and machines have been designed to meet many different requirements. Some applications demand high torques for momentary or intermittent use, while others need high efficiency for continuous operation. Two-pole machines have a synchronous speed of 24,000 rpm and normally operate at 22,500 rpm when fully loaded. The larger sizes develop double full-load torque with 3 to $3^1/_2$ times full-load current.

The control regulates the a-c power supply, furnishes 14 or 28 volts direct current for battery charging and d-c auxiliaries, establishes satisfactory parallel operation, and practically eliminates radio or audio interference. The electronic voltage regulator, which has been developed, is faster in response than the mechanical type. Simpler and more positive antihunting methods are obtainable for less weight. It is both a regulator and exciter in one device since d-c field power is provided by rectification from the a-c bus. The regulating tubes are in duplicate to assure reliability. An intermittent-rated Rectox and transformer cause the alternator to build up from its residual magnetism. This function is under the control of a small "Silverstat" regulator which corrects for temperature variations in the circuit resistance. The transfer to electronic regulation is automatic by means of a small thermal timing relay. This method of initial build-up is necessary since sufficient time must elapse for the electronic regulator tubes to reach operating temperature before field current is obtained by rectification.

The engine driving an alternator is started and automatically idled until it reaches operating temperature after which it comes up to normal speed. The alternator switch is then manually placed in the "build-up" position and the voltage rises to normal value under self-excitation and magnetic voltage-regulator control. After some 45 seconds, during which the filaments of the electronic regulator have reached normal operating temperature, the alternator control switch automatically trips to the "run" position. The machine is then under electronic regulation and may be connected to the main bus by closing a circuit breaker. When a second unit is started and is under electronic regulation it may be connected to the bus by closing the circuit breaker. If a reversal of power occurs manual-reset wattmeter contacts function to disconnect the alternator from the bus.

The battery-charging unit consists of a dry-plate rectifier fed from a three-phase transformer through a tap-changing device under control of a mechanical voltage regulator. The rectified voltage is maintained practically constant regardless of load and ambient temperature changes. A central control station contains the alternator circuit breakers, the manually operated build-up switch, and necessary metering equipment.

The 110-volt 400-cycle three-phase system is suitable for lightweight radio equipment and is practical for three-phase induction motors. The use of three wires in conduits, together with the

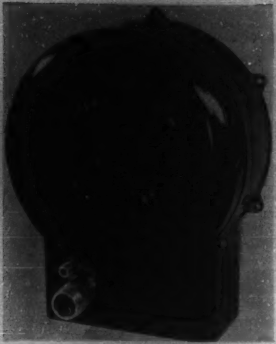

Figure 6. This 4,000-rpm aircraft generator is rated 5 kw, 28.5 volts, 175 amperes. It has a five-minute rating of 7.5 kw. The total weight including the starting switch is just over 50 pounds

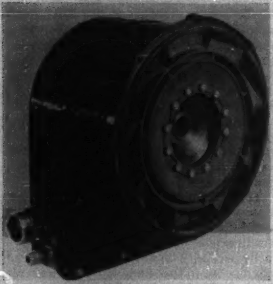

Figure 7. This aircraft generator is in the featherweight class and weighs slightly over 40 pounds including the starting switch. It is rated 5 kw, 28.5 volts, 175 amperes, and will carry 7.5 kw for five minutes. It runs at 6,000 rpm

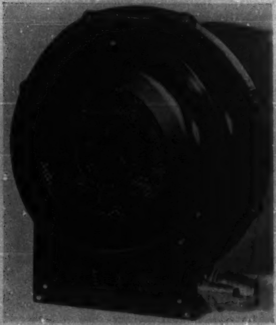

Figure 8 (left). This aircraft generator runs at 3,200 rpm and weighs just under 70 pounds including the starting switch. It is rated 5 kw, 28.5 volts, 175 amperes, and will carry $6^3/_4$ kw for 15 minutes

proper balance of single-phase loads between the three phases, avoids the impedance drops which occur with single phase. Motors will start and produce rated outputs without the use of centrifugal switches, external capacitors, and other control devices. Thus, the system is well adapted for application on large airplanes which make extensive use of electric power and have heavy motor loads.

24-Volt D-C System

The 24-volt system is becoming a standard on airplanes using d-c auxiliary power. Generators have been built which are rated five kw, 28.5 volts, 175 amperes and will carry short-time overloads of 150 per cent normal capacity. Operating speeds are 3,200, 3,430, 4,000, and 6,000 rpm and are determined by the available prime movers. In the case of the 6,000-rpm machine the engine runs at 3,000 rpm. Machines are designed with magnesium-alloy supporting brackets and housings to assure light weight. Fans are magnesium, aluminum, or a heavier metal depending on the added flywheel effect needed for the engine when the armature weight is insufficient. The effectiveness of this weight varies directly as the square of the radius and the fan is the largest-radius rotating member. Special iron alloys are used for the magnetic circuit. Insulation is composed entirely of glass, mica, and asbestos. Generator armatures and fans are mounted on shaft extensions and stators are bolted directly to engines.

It appears that motor speeds will remain at or below 10,000 rpm. The inherent limitations of armature construction and the high starting torques required tend to limit maximum speeds. Motors which have been built run at 7,500 rpm as compared with the much higher speeds practicable with a-c induction types. The materials used and the insulation are essentially the same as for generators.

The control regulates the d-c power supply and furnishes charging current for a small battery. It automatically disconnects the battery when the power plant is shut down and functions with little radio or audio interference. The voltage regulator is a small lightweight device utilizing a modification of the industrial Silverstat. Contact maintenance is practically eliminated by distributing the regulating duty over 15 to 20 contacts, each operating safely below the "sparking voltage". Rocking-type bearings, spring restrained, minimize friction and wear.

Change in regulated voltage during the warm-up period has been reduced by using low-temperature-coefficient wire in the regulator coil. Correction for ambient-temperature variation is provided by bimetal compensation of the calibrating-spring tension. The ratio of battery capacity to that of the generator is small, which makes it necessary that the reverse-current device drop out at a small current

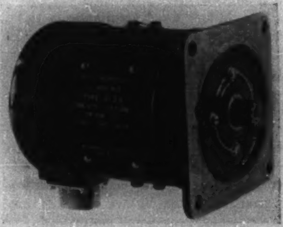

Figure 9. This aircraft motor develops five-eighths horsepower at 25 volts and 7,500 rpm. It weighs close to seven pounds complete

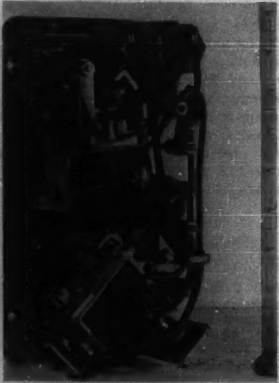

Figure 10(right). This aircraft voltage regulator and reverse-current switch is applicable to the 12-volt d-c system

It weighs under four pounds and maintains accurately regulated bus voltage for 15-volt main-engine-driven aircraft generators

Figure 11. This aircraft voltage regulator and reverse-current relay handles the 24-volt d-c system

It maintains 28.5 volts at the bus. The complete weight including cover is less than nine pounds

value. The relay closes when generator voltage is one volt above battery voltage and opens on less than ten amperes reverse current. It operates the generator contactor which has silver contacts of adequate capacity to handle 175 amperes rated current. By using the generator as a motor to start the engine there is no need for a separate starting motor and its coupling. This combination of functions reduces equipment and cable weights since a separate heavy starting-motor circuit is unnecessary.

The 24-volt d-c system appears to be best for standardizing on one potential for a number of different sized airplanes. It is possible to handle readily battery charging without upsetting present standards. Two 12-volt batteries are applicable, thus facilitating changing from 12 to 24 volts by having 12 volts available during the changeover period. The 24-volt system can be employed advantageously on the lighter types of airplanes which have small motor loads.

New A-C and D-C Apparatus Available

The past 18 months has been a period of intense development of auxiliary engines, generators, motors, and control for airplanes. The two systems now available—110-volt 400-cycle three-phase a-c and 24-volt d-c—meet present requirements and provide for future increases in the use of electric power. The former is well suited for large airplanes with predominating motor loads and the latter is an applicable standard for medium-sized craft with light motor loads.

Discussion

V. H. Grant (United States Navy Department, Washington, D. C.): Mr. Clardy has presented some interesting points on a-c power for aircraft. The Navy, having at least as extensive and complex aircraft electrical systems as exist today, has been undertaking a comprehensive research program on electric power for airplanes. Our results to date do not check entirely with Mr. Clardy's analysis, and a brief summary of our points of difference may be of interest.

First, auxiliary engines for driving generators are extremely expensive, as compared to main-engine drive, in reduced airplane performance and lower useful or pay load. An analysis which we made recently indicates that a 50,000-pound plane suffers less loss in performance by diverting 50 horsepower for auxiliaries from the main engines than in carrying additional auxiliary engines and the extra fuel and oil which they require.

Second, a twin-engine airplane with two auxiliary engines is actually a four-engine plane, insofar as maintenance and overhaul are concerned. The small engines are almost as complex to overhaul as are main engines.

Third, valuable space in the plane must be appropriated, and made soundproof and fireproof, for auxiliary engines.

Fourth, auxiliary engines present an unnecessary additional target, in the case of military planes.

True, main engines are "cleaned up" by the use of auxiliary engines, and a constant drive speed is obtained, permitting the use of a-c generators but these advantages are gained at a considerable penalty. And, whether we want alternating current after we have provided for its generation is questionable, at least for our peculiar requirements. Some of the arguments on this matter may be summarized as follows:

1. Practically all our motors are of the momentary-duty type, requiring high starting torque; they are designed on the basis of torque rather than heating. A d-c series motor is ideal for this service.

2. D-c generators use simple regulators and may be paralleled easily.

3. Battery stand-by may be used for vital services and for peak loads.

4. Much of our load, if alternating current, would be operated from a single-phase source. Load balancing during emergency operation would probably keep the poor flight engineer too busy to do anything else.

5. Voltage diversity would be simplified, but, to date, radio equipment, the only load requiring voltage change, cannot be operated in parallel with fluctuating power loads, owing to the light weight master oscillator circuits being very critical of supply voltage.

6. High-speed motors, although very light in weight, require gear reducers of considerable weight to provide usable speeds. Starting these motors with their low torque, at low temperatures with the gear box grease congealed, may be a problem. Also, the matter of bearing design and lubrication is by no means solved.

7. Conductor weights are smaller with direct current due to fewer wires, and to the absence of the power-factor problem; the power factor of an induction motor when starting is notoriously low.

Mr. Clardy has mentioned high efficiency of equipment. Our studies, so far, indicate that generators, conductors, motors, etc., should have just about as low efficiencies as possible without burning up. The reason is, of course, the weight saving possible by "forcing" the equipment far beyond its maximum efficiency. Weight, in general, appears to be more important in determining airplane performance than power input.

It is the intent of my remarks to promote further discussion and thought on this matter, which is by no means settled. The Navy will benefit as much as anybody from the final solution to the aircraft auxiliary-power problem, and will appreciate any other remarks.

W. J. Clardy: Aircraft auxiliary-engine-driven power plants appear essential for ground or sea-level service in order to avoid main-engine operation for furnishing auxiliary power. Increase in the use of such units will, naturally, lead to improvements to give better weight efficiency. The accessibility, dependability, and small size of the auxiliary engine makes it relatively simple to inspect and maintain. Growth in the use of electric power on airplanes has stepped-up generator sizes. Gear boxes and drive shafts are needed for main-engine drives and the mechanical problems become acute in the case of large units. A main-engine-driven generator, drive shaft, and gear box should be just as good a target as an auxiliary-engine-driven generator—perhaps better since fire may be concentrated on main engines.

The 110-volt 400-cycle three-phase a-c system has been developed to meet the demand for more power—10, 12.5, and 20 kva in single power plants. Alternators are easily paralleled by merely bringing a second machine up to speed and closing the circuit breaker to connect it to the line. Batteries and battery chargers are used with the a-c system but it seems desirable to keep such heavy power sources to a minimum in the interest of weight economy. The proper balancing of single-phase loads can be worked out in advance of any emergency. It is entirely practicable to build light-weight radio equipment for the 110-volt 400-cycle three-phase system and voltage regulation is extremely accurate.

Light-weight high-speed induction motors are well adapted for 400-cycle three-phase operation. High starting torques are obtainable and alternators are designed for high current overloads at lowered power factors to avoid impairment of voltage regulation. Two-pole induction motors run at 24,000 rpm synchronous speed. Lower speeds are secured by increasing the number of poles. In a weight analysis it is necessary to include gearing required for a motor but even on this basis high speed is advantageous. This seems to be borne out by the universal trend to higher speeds. A lubrication system has been evolved for 24,000-rpm motors which appears to be satisfactory under all service temperature conditions.

An airplane with an extensive motor load requires high voltage to avoid exces-

Some Impulse-Voltage Breakdown Tests on Oil-Treated Paper-Insulated Cables

C. M. FOUST
MEMBER AIEE

J. A. SCOTT
MEMBER AIEE

Synopsis: Data are presented on impulse-voltage breakdown values obtained on oil-treated paper-insulated cables over the insulation thickness range from 0.187 inch to 0.600 inch. The average stress at breakdown approximates 1,600–1,700 volts per mil. High-density papers show some superiority over ordinary-density papers. Cathode-ray oscillograms of the testing wave ($1^1/_2$x40 impulse wave—positive polarity) before and at breakdown are included for a typical test.

INFORMATION on the impulse strength of high-voltage apparatus has accumulated steadily in the last 20 years due particularly to advances in technique of generation and measurement of high-voltage surges. Line insulators, bushings, transformers, and other apparatus have been tested. Cables have received attention during the last decade of this period, and the literature is beginning to record this information.[1,2]

This paper presents data on the impulse breakdown voltage of oil-treated paper-insulated cables over the range of insulation thickness from 0.187 inch (0.472 centimeter) to 0.600 inch (1.520 centimeters). The impulse breakdown voltage at the latter thickness was of the order of 1,000,000 volts. Cable breakdown tests are necessarily destructive of the sample and involve many samples and a costly preparation procedure. Data thus accumulate more slowly than in cases involving air flashover. These data have been accumulated over the period 1931 to 1938. The testing technique has differed somewhat during this period; early tests employed a 1x10 wave (that is, one microsecond to crest voltage, ten microseconds to decrease to one-half crest voltage); later tests employed a $1^1/_2$x40 wave. In all cases a positive impulse was applied to the cable conductor, the lead sheath being connected to ground.

The tests on the thinner (0.187 inch) insulation were made on samples having ten feet of lead. The ends were built up with a varnish-cloth reinforcement over which was placed a spun-copper stress-distributing bell. This latter was connected to the sheath by a closely wrapped spiral copper braid on the lower slope of the varnished-cloth reinforcement. The whole cable was then immersed in an oil-filled tank. All other tests were made on 16-foot (lead length) samples using standard porcelain oil-filled terminals of usual design. All cable failures secured were in the leaded portion of the cable.

Impulse Generator

The impulse generator used for these tests has a 2,000-kv open-circuit rating and is of the parallel-charging, series-discharging type. The d-c charging voltage is 200 kv for each of the ten parallel capacitor banks. The generator has a series capacitance of 0.0067 microfarad and a circuit inductance of 75 microhenries.

The circuit arrangement used is shown in figure 1. The wave-front time is determined by the resistance-capacitance combination R_1C_2 and the wave tail by the resistance R_2 and the combined capacitances C_1 and C_2. The determination of these values is done experimentally and without delay on the oscillograph electric-transient analyzer.[3,5] All oscillograph records were taken with the type *HC*-15[4,5] hot-cathode high-vacuum high-voltage cathode-ray oscillograph.

Demonstration of Measurement Accuracy

Standard procedure used in these tests for calibration of the surge generator is given in the recently revised AIEE Standard No. 4, "Measurement of Test Voltage in Dielectric Tests". This calibration recommends an intercomparison between sphere gap and cathode-ray oscillograph for demonstration of measurement accuracy. These intercomparisons were made at frequent times during this cable-testing program. Record of one such comparison is reproduced in table I. The deviation between sphere gap and oscillograph

---

sive weight in the distribution lines. This seems to eliminate the 24-volt d-c system when a large number of motors is used. At 110 volts, the 400-cycle three-phase a-c system offers some attractive weight-economy possibilities because of high-speed induction motors. In considering auxiliary-power-plant efficiency on airplanes it is obvious that "weight efficiency" is the determining factor. In the analysis of an auxiliary power system there is no question about its importance. "Weight efficiency" requires consideration of the fuel, oil, engines, generators, control, distribution system, motors, lights, radio, and any other loads. The efficiency of a specific part of the system must be selected to attain the lowest total weight.

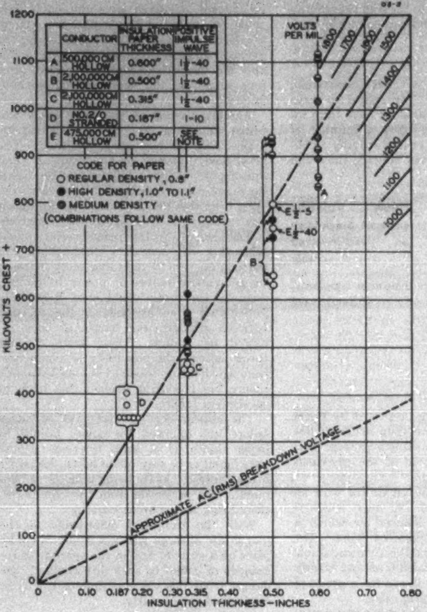

Figure 3. Summary of impulse tests on cable insulation

wave shape and its excitation calibrated in terms of crest kilovolts, an impulse was applied to the cable of a magnitude well below (approximately 50 per cent) expected breakdown. Successive single waves were then applied, each exceeding the previous wave by an approximately constant increment until a cable-insulation breakdown was obtained. Failure was indicated in the tests made in 1931 by the action of a surge-crest ammeter[6] inserted in the ground lead from the cable sheath; in all tests made since that time a cathode-ray oscillograph[4] was employed using a resistance voltage divider, and an oscillogram was obtained of each wave up to and including the one causing failure. The magnitude of the crest voltage was obtained from the cathode-ray oscillograph deflection and voltage-divider ratio as indicated in table I. Practically all failures occurred on or near the crest of the wave.

Specimen Record

A specimen oscillograph record is reproduced in figure 2 wherein are recorded the six full ($1^1/_2$x40) waves at increasing voltage amplitudes followed by the wave at 490 kilovolts crest which caused cable failure. The eighth record is that of a 500,000-cycle timing wave and the ninth a deflection calibration. The data pertaining to all these are given in table II. The recorded waves were analyzed to be 1.55 microseconds to crest and 39.3 microseconds to half value on the wave tail.

Results

Figure 3 shows the results obtained in these tests. Plotted here is kilovolts crest against insulation thickness. Table III records the numerical values. No attempt has been made to draw a curve through the points. In fact, the dispersion is such that a straight line fits the data as well as does a curve. A polar-co-ordinate system has been superimposed from which the average stresses (volts per mil) may be read. An average figure of 1,600 volts per mil may be carried in mind as representative.

It is not attempted to take account of the stress variation between conductor and sheath, although conductors from number 2 Brown and Sharpe to 2,100,000-circular-mil hollow with outside diameters of 0.420 inch and 1.890 inch respectively were used. The tests included several grades or densities of papers, and in general the denser papers gave higher breakdown values. In the presence of the natural variation or dispersion of the results, including the fact that many samples included graded insulations, an accurate statement cannot be made comparing the different densities. We may perhaps infer that the dense papers yield results 10–15 per cent better than the lower-density papers.

The results reported in this paper are in excellent agreement with those reported by Held and Leichsenring,[2] who tested over nearly the same range of insulation thickness.

All the tests here reported were made with positive polarity and with waves of 1 to $1^1/_2$ microseconds wave front. However, as far as analysis of breakdown values reported herein are concerned, the wave-shape change is not important. The wave fronts were practically the same, and failures occurred most frequently on or near the wave crest. A 1x10 wave was used on the earlier tests as a compromise between the 1x5 and $1^1/_2$x40 waves then most common. Later, as the 1x5 wave diminished in use, all tests were made with the $1^1/_2$x40 wave. These waves are those in most common use in this country for impulse testing.

Discussion

Herman Halperin: See discussion, page 399.

P. L. Bellaschi and W. L. Teague: See discussion, page 400.

L. G. Smith: See discussion, page 401.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): Several years ago tests were made in the high-voltage engineering laboratory in Pittsfield to determine the volt-time characteristic of a cable. Although in general high-voltage cables probably are not subjected to steep-fronted lightning waves, it might be of interest to publish the result.

The cable sections tested were prepared similarly to the samples described in the paper with the exception that the leaded portion was only ten inches long as compared to ten feet in the paper. The total length of a sample was 4½ feet. The whole section was immersed in oil. All failures occurred in the leaded section.

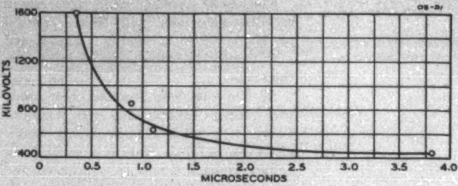

Figure 1. Volt-time curve of breakdown on lead-sheathed cable

Negative polarity, 1.5x40 wave

The cable had a conductor of 500,000 circular mils, 0.281-inch paper insulation, oil treated, and a total outside diameter of 1.6 inches. Tests were made with negative polarity.

For determining the minimum breakdown strength, tests were started at a voltage of approximately 60 per cent of the expected failure voltage. Voltage was raised in about 25-kv steps until failure occurred at 440 kv. Two impulses were applied at each step.

The breakdown voltage thus obtained is probably somewhat too high for design purposes, because it does not take into account the effect of successive strokes on the breakdown. In transformer insulation the damaging corona level is reduced to 80 per cent of the single-shot corona level, when 15 or more impulses are applied. In a cable with its more uniform field and uniform insulation, the multishot breakdown probably is not quite as much lower as in transformer insulation but nevertheless their effect must be taken into account to arrive at the proper safety factors.

The other three sections were tested by applying various amounts of overvoltage to the cable and recording the resulting failure by means of a cathode-ray oscillograph. For the purposes of the investigation described, the few breakdown points obtained showed results which gave a sufficiently consistent curve as shown in figure 1 of this discussion. However, a greater number of points and different thicknesses of insulation would have to be investigated for design data.

Of interest is a comparison of the overvoltage characteristics of various electrode shapes in comparison with the cable. This is shown on figure 2 of this discussion for a 20-inch rod gap, a 10-centimeter sphere gap at 20 centimeters spacing and the cable.

It is interesting to note that the cable in spite of the relatively uniform field has a much steeper characteristic than the sphere and even approaches the characteristic spark-over curve of the 20-inch gap at 0.5 microsecond. The reason for this behavior may be imperfections in the lead sheath producing point effects and corona on the positive sheath.

R. W. Atkinson (General Cable Corporation, Perth Amboy, N. J.): In regard to surge strength of paper in cable we have been for some time depending upon a number of tests made in 1931. It is gratifying to observe the close agreement between these and the more complete series reported by Foust and Scott. Besides our data in direct line with Scott's we are reporting here some tests tending to answer some of the questions which have been asked.

Our tests were made on cables with an insulation thickness of 190 mils, which is identical with the thickness on which a number of tests were made by Scott. The average value of 12 tests directly comparable with his was 348 kv, which is almost exactly the same as the value shown for a group of his tests on corresponding cable.

The tests included in the above group were all made with surges of positive polarity. A few tests were with surges of negative polarity. These required slightly higher voltage to produce breakdown than required for breakdown of similar cable tested with positive polarity.

Half of the samples were made with paper of high density and half of lower density. The average strength of those with high-density paper was 18 per cent greater than for those of low density. It is noted that this is somewhat greater than found by Scott but reasonably comparable with his figures.

Two longer lengths were subjected to 83 and 115 repeated surges respectively. In the first surges, the applied surge voltage was about 60 per cent of the expected surge breakdown. Ten shots were applied after which the applied voltage was increased by about 6 per cent of the expected breakdown. A third set of ten shots at 6 per cent higher voltage was then applied, after which successive sets of ten shots each were applied with voltage increments of 3 per cent until failure occurred.

While the voltage of the ten successive shots at one setting was substantially the same, this repetition would not be exact. Thus the fact of failure at other than the first shot at one voltage may be due either to the cumulative effect of successive shots at substantially the final breakdown value or may be due to a slightly greater voltage at the surge producing failure than on the preceding surges at the same nominal voltage.

On one of the lengths, 35 of the shots were at a value within 10 per cent of the average surge breakdown of similar cable and the breakdown occurred after the cable had stood two surges at the breakdown setting. On the other, 33 of the shots were above the average surge breakdown of similar cable and the surge breakdown occurred after four surges at the same setting without failure.

Another portion of the same cable was tested similarly at 60 cycles but without the application of the surge voltage. The breakdown voltage on the "surged" and "unsurged" samples fell within the same range and thus there was no evidence from these tests that the 100 surges had produced any reduction in strength of the insulation.

The tests of this last named series appear reassuring with respect to the possibility of partial puncture by lightning being followed by subsequent failure at power frequency. Actually the result could have been fully anticipated from analysis of the relation between strength and length of time required for failure. These tests do not throw light on the possibility of a puncture from lightning not followed at once by power failure, but producing damage that leads to subsequent failure.

The appearance on dissection of surge failure not followed by power failure in paper cables, is of some interest. These were found to be tiny radial holes, the paper being "burred," as by being punctured by a minute fast projectile from the conductor, there being no apparent burning.

With the increasing knowledge of the magnitude of surge voltages which can take place on a system, and of the amount of resistance of cables to such disturbances, the danger from this cause of failure has been diminished very greatly.

L. I. Komives (nonmember; The Detroit Edison Company, Detroit, Mich.): First of all the authors of this paper are to be congratulated for the valuable data which they collected in a field largely unexplored.

1. I am rather puzzled with the results presented in this paper because the voltage

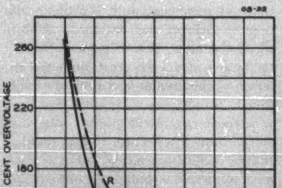

Figure 2. Negative-voltage characteristics

C—Cable, 0.281-inch oil-treated paper (440 kv critical)

R—Rod gap (410 kv critical)

S—Sphere gap (450 kv critical)

100 per cent equals critical breakdown voltage

gradient seems to have had no effect whatsoever on the impulse strength of the cables tested by the authors. In our rather incomplete experiments we found that the voltage gradient has a very strong influence on the impulse strength.

2. We have also found that uniformity of the taping has a very decided influence on the impulse strength. No mention whatsoever was made in the paper in this respect.

3. I feel that the results shown on small-size copper conductors (samples 1 to 7—table III) are due to a highly viscous oil used in these cables in contrast with the much lower viscosity oils of the rest of the samples. I would like to know whether the authors concur with this explanation.

4. We feel that it is perhaps of more importance to cable users to know just what the impulse strength of a piece of cable is when tested with the maximum potential available. Although the general opinion is that potentials lower than those causing breakdown of the insulation have practically no effect on the insulation because of the short time involved, we have reasons to believe that every application weakens the insulation and therefore, testing cables with consecutively high potentials does not indicate the true impulse strength of the insulation.

5. I would like to know what the "medium density" paper mentioned in table III of the paper is.

Wm. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): The following questions occurred to me in reading the paper:

1. Would any materially different values of volts per mil have been obtained if actual rather than nominal insulation thicknesses had been used?

2. Were any of the cables shielded with copper shielding tapes? Would the use of such tapes, by holding the paper tapes firmly together, increase the impulse strength?

3. With unexplained variation of impulse strength from 1,300 to 1,900 volts per mil on one wall thickness, is it safe to base insulation walls on impulse strengths higher than 1,300 volts per mil?

4. Figure 1 shows a resistor R_1. Is there any reason for preferring this to a reactor?

C. M. Foust and **J. A. Scott:** In J. H. Hagenguth's discussion he has added three front-of-wave short-time breakdown values and a minimum breakdown value on 0.281-inch paper to our test data. The minimum breakdown value is a good check on our values for this thickness, being almost exactly on our average curve. The three short-time values permit an approximation of the volt-time curve from actual test data on cable samples down to 0.4 microsecond. The comparison of rod gap, cable, and sphere gap volt-time curves wherein the cable curve conforms more nearly to the 20-inch rod-gap curve than to the spheres suggests a long breakdown path, possibly in many parts parallel to and between paper layers.

The authors appreciate the discussion contributed by Messrs. Bellaschi and Teague, pertaining to volt-time breakdown relations for short time periods. Other than that the point of breakdown on the wave shape was recorded by cathode-ray oscillograph, no effort was made in our work to gather data on volt-time relations. As pointed out in the paper, all failures occurred at the crest or a short time after, indicating very little increase in voltage down to 1.5 microseconds for wave-crest failures. This, the authors presume, is the basis for the statement by Messrs. Bellaschi and Teague that the volt-time characteristic is essentially constant down to one or two microseconds. However, Mr. Hagenguth's data which was taken on the wave front indicates a 20-per cent increase in voltage at 1.5 microseconds. This is likely due to the fact of the wave-front failures being higher than wave-crest values at the same time point.

In commenting on L. G. Smith's discussion, he is correct in presuming that the values are for new cable. We agree that similar data on cable having been in service for some time are desirable. It seems logical to expect that there should be no change in impulse strength with age for oil-filled cable, while solid-type cable might show a decrease due to void formation. The point of variation of breakdown strength with conductor size has been twice referred to in the discussion with the inference that our tests showed no such variation. We did not wish to convey this impression. To determine such a relation accurately would require a large number of tests with different sizes of conductors and a range of insulation thicknesses for each. Such a test program on high-voltage cable samples is quite formidable. We wish to say that because of the dispersion of our test points analysis of the data did not provide us with a sufficiently definite relation between conductor size and breakdown to warrant comment.

Mr. Atkinson has referred to a considerable group of data taken by his company. He had very kindly made these results available to us early in our investigation. To show the good agreement between these results as well as those reported by Held and Leichsenring (reference 2 of the paper), figure 3 of this discussion consolidates these together with some other data identified in the figure. It is here seen that all data from some six sources are in excellent agreement. An excellent idea of the spread of the values is given. This spread is very reasonable for such breakdown values.

Mr. Atkinson also refers to the lack of damage done by impulses of value somewhat below the breakdown value. This freedom from so-called "impulse fatigue" is verified in our own experience. For example, in our tests on the samples having 0.187-inch paper, two additional samples were subjected, one to 100 impulses at 325 kv, the other to 500 impulses at 300 kv; following this single impulses at 25-kv increments were applied. Both cables failed at 375 kv which compares with the highest results obtained on samples 1 to 7 reported in the paper. However, an open mind should be kept on this subject, as indeed on all aspects of this relatively young subject, for we have seen unpublished data from abroad where on relatively thin samples several thousand successive shots did produce a decrease in the breakdown value.

In reply to Mr. Komives in the order of his questions:

1. We would agree that voltage gradient is probably the controlling factor in the breakdown

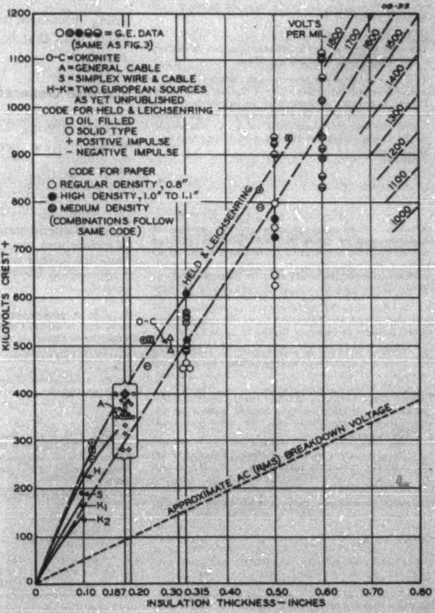

Figure 3. Summary of impulse tests on cable insulation

Impulse Strength of Cable Insulation

E. W. DAVIS
FELLOW AIEE

W. N. EDDY
FELLOW AIEE

INSULATED CABLES often are exposed to lightning and often have been damaged by lightning, especially rubber- or cambric-insulated cables of medium or lower voltage. It is also true that some service trouble has been improperly attributed to lightning. Knowledge of the impulse strength of cable insulation is necessary to analyze such cases correctly and to minimize lightning trouble by proper cable design. In spite of the practical need for such information there seems to be a conspicuous lack of it in the literature.

From time to time for several years we have been making impulse tests on cable insulation, either as we needed the data or as we got the opportunity. As a result we have accumulated a general assortment of data without conducting a complete or continuous investigation. We have found these data worth while and hope eventually to make the data complete enough to merit a more detailed analysis than seems justifiable at present. In the meantime we are reporting the results to date with the hope that the ensuing discussion will uncover results of other tests that have been made but not reported.

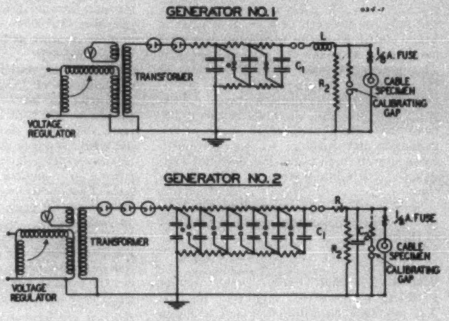

Figure 1. Connections

Impulse Generators

Each testing impulse consists of a nonoscillatory increase and decrease of voltage at a definite rate. Two different impulses have been used for these tests, a 1x10 wave and a 1.5x40 wave. The first figure in each designation is the time in microseconds from the beginning of the impulse to the crest of the impulse. The second figure is the time in microseconds from the beginning to the point on the impulse tail at which the voltage has fallen to one-half the crest or maximum value.

The impulses are generated by discharging a capacitance through a resistance. The resulting voltage drop across the resistance is the impulse. The shape of the impulse is controlled by the values of the constants in the discharge circuit; the impulse front by inductance in series or capacitance in parallel with the resistance and the impulse tail by the resistance itself. The assembly necessary to produce these impulses constitutes the impulse generator.

Figure 1 shows the connections of the two generators that were used for the tests. In both, the necessary high discharge voltage is attained by the familiar Marx circuit which has been fully described in the literature. The differences between the two generators are evident from the connections in figure 1 and the ratings and circuit constants in table I.

Generator 1 was made several years ago, using available glass plates for the main capacitance. The constants in the discharge circuit were adjusted for a 1x10-microsecond wave because this was the intermediate of the three waves then in common use for testing lightning arresters.

Generator 2 was built more recently, in order to enlarge the range of sample length and size that could be tested. The discharge circuit was adjusted to a 1.5x40-microsecond wave because this

Paper 40-34, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 29, 1939; made available for preprinting December 21, 1939; released for final publication February 29, 1939.

E. W. Davis is chief electrical engineer and W. N. Eddy is experimental engineer, Simplex Wire and Cable Company, Cambridge, Mass.

The data in the paper represent the efforts of several people at irregular intervals over the last four years. In particular the authors wish to acknowledge the valuable advice of C. M. Foust in building generator 2 and the conscientious work of S. N. Alexander, W. D. Fenn, and Oscar Hess in calculating and testing.

---

strength. It is, however, only one of a number of variables and we chose the more practical minded way of plotting breakdown against insulation thickness. Conductor sizes are given so that approximate maximum gradients may be calculated if desired.

2. We felt that the uniformity of taping was excellent and found no indication from the examination of the failures to indicate taping to be at fault.

3. We see nothing in our results to lead us to attribute different performance to the two different viscosities of oil used. As a first approximation we would assume them to be identical. Samples 1 to 7 of table III have thinner insulation than the remainder and consequently benefit somewhat by any curvature that may exist in the breakdown voltage-thickness curve.

4. The alternative method of testing referred to by Mr. Komives is highly interesting. We proceeded the way we did because we were on untried ground and we preferred to feel our way along as it were. Our results we feel are more indicative of the lowest breakdowns that might be obtained and consequently more useful in estimating safely sustained voltage values. However, the procedure suggested has its merits and will, we hope, be used. We have already referred to "impulse fatigue" in connection with Mr. Atkinson's discussion.

5. The medium-density paper was a special paper having a density of 0.85 or lower.

Mr. Halperin emphasizes nicely a number of points and gives some valuable suggestions for further work.

Answering Mr. Del Mar in the order of his questions:

1. The difference between actual insulation thickness and nominal thickness was small compared with the variation in breakdown-voltage results.

2. No shielding tapes were used. Since all tests were made on single-conductor cables, which were newly manufactured and whose sheaths had not been expanded by heating and cooling cycles, our results should be the same as if shielding tapes were used.

3. Mr. Del Mar's third question covers a lot of ground. To answer it briefly our consolidated data between 0.315-inch thickness and 0.600-inch thickness regardless of the particular construction of the cables (paper, etc.), indicates the probability that five per cent of such a group of cables would fail at 1,300 volts per mil or less. (Average breakdown, 26 tests = 1,615 volts per mil; $\sigma = 191$ volts per mil or 11.8 per cent of average.) Such variation is typical of breakdown data.

4. Other circuits, of course, than that shown in figure 1 may be used. We preferred a resistor, R_1, to a reactor because of the lesser liability to oscillations which frequently occur when lumped reactors and capacitors are used.

shape had become generally accepted as the standard test wave. The ballast capacitance in parallel with the sample has two functions; to help control the wave shape and to decrease the effect of changing sample capacitance on the wave shape.

Our principal purpose in making these tests was to compare different sizes and types of cable on an impulse reasonably representative of lightning, without attempting to get co-ordination with other impulse data in the literature. Therefore, we have been more interested in keeping our wave shape constant or fixed than in making sure it was exactly 1x10 or 1.5x40. For this reason we have not yet considered it necessary to acquire a cathode-ray oscillograph and our wave shapes therefore have not been confirmed by oscillograph. The test results in table II indicate that the value of our results is not seriously reduced by this omission.

Each test is made by increasing the charging voltage in seven-kv steps usually beginning at 50 per cent of the estimated breakdown voltage. Each voltage is held constant while two successive impulses are applied to the sample by lowering a third sphere into the first-stage gap. Failure of the sample is indicated by explosion of the one-eighth-ampere fuse wire in series with the sample. The test voltage is indicated by a voltmeter coil in the charging transformer calibrated in terms of a sphere gap in parallel with the test sample. Both ends of the sample are connected together. Various arrangements of the sample were tried without finding any effect on the impulse strength.

Table I. Ratings of Impulse Generators

	Generator 1	Generator 2
Maximum discharge voltage at terminals of C_1 (kv)	300	600
Maximum voltage on specimen (kv)	260	550
Main capacitance C_1		
(μf per 50 kv)	0.04	0.5
(μf at full voltage)	0.0067	0.042
Ballast capacitance C_2 (μf)	None	0.0048
Discharge resistance R_1 (ohms)	None	115
R_2 (ohms)	2,300	1,100
Calculated wave shape	1x10	1.5x40

Table II. Effect of Wave Shape on Impulse Strength (Volts Per Mil)

	Generator 1—1x10 Wave			Generator 2—1.5x40 Wave		
	Average	Maximum	Minimum	Average	Maximum	Minimum
Cambric	1,050	1,120	1,000	1,090	1,150	1,050
Rubber	1,080	1,300	900	1,070	1,240	915

Table III. Effect of Impulse Polarity on Impulse Strength of Rubber-Insulated Wire

Wire Size	Insulation Wall	Impulse Polarity	Impulse Strength in Volts Per Mil			Ratio, Positive/Negative (Average)
			Average	Maximum	Minimum	
No. 6 solid	$^{6}/_{64}$-inch	Positive	1,033	1,150	900	0.84
		Negative	1,225	1,300	1,200	
No. 6 solid	$^{10}/_{64}$-inch	Positive	1,400	1,550	1,250	1.09
		Negative	1,290	1,450	1,150	
No. 6 solid	$^{14}/_{64}$-inch	Positive	928	1,050	780	1.02
		Negative	905	1,000	850	

Figure 2 shows the general arrangement of generator 2. At the left is the portable control table connected to the generator through two multiconductor portable cables. The voltage regulator controls the input to the transformer in the corner which through the tube rectifiers charges the capacitors on the wooden rack. The stage resistors consist of water in the garden hose visible along the upper edge of the rack. The third or trigger sphere is visible just above the first stage gap. A sample of plain rubber wire is shown ready for test in water. The series fuse wire is on the framework above the water drum. The motor on the floor is circulating a sodium carbonate solution through the vertical hose for R_1 and R_2. The capacitor bank at the right is the ballast capacitance or C_2.

Effect of Wave Shape on Impulse Strength

These tests were made on five-foot adjacent samples taken from two lengths of single-conductor cable, number 6 solid, $^{6}/_{64}$-inch wall of insulation, lead sheath, one length insulated with rubber and one with varnished cambric. In table II are the results in volts per mil wall, the average, maximum, and minimum of five tests. Samples from both lengths were tested with each of two different impulse wave shapes, 1x10 and 1.5x40.

The results show no definite difference in strength between the two wave shapes in spite of the considerable difference in shape. One wave is 50 per cent slower than the other on the front and four times longer than the other on the tail. This lack of a real difference in strength between the two waves is good evidence that a reasonable deviation in our wave shape from the calculated should have no appreciable influence on the test results, and therefore that the lack of an oscillograph should not seriously limit the value of the test results.

This lack of difference also indicates that any conclusion based on either shape should hold for the other shape and for a fairly large range of impulses occurring in actual service.

Effect of Impulse Polarity on Impulse Strength

Table III shows the effect of impulse polarity on the impulse strength of three

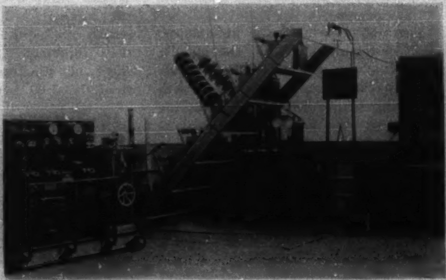

Figure 2. Generator 2

Table IV. Effect of Electrode Surface on Impulse Strength (Volts Per Mil)

	Average	Maximum	Minimum
Lead sheath	1,400	1,490	1,300
Rubber surface in 0.1 per cent salt water	1,390	1,440	1,300
Lead foil wrapped around rubber insulation	1,410	1,480	1,340

different sizes of rubber-insulated wire. The tests were made on five-foot samples with generator 1 and the 1x10 wave.

On the average no real difference in strength is indicated between the two polarities. Unless specified otherwise all other tests reported in this paper were made with the negative polarity.

Impulse Strength of Rubber-Insulated Wire—Effect of Electrode Surface

Table IV gives the results of tests made on five-foot samples of number 6 solid, $^6/_{64}$-inch wall of rubber, using three different kinds of outer electrode surface. All tests were made on generator 2 with the 1.5x40 wave. The results are in volts per mil wall, average, maximum, and minimum of at least five tests.

These results show that any one of these types of outer electrode can be used indiscriminately. In most cases the salt water is most convenient for testing rubber-insulated wire.

Impulse Strength of Rubber-Insulated Wire—Effect of Specimen Length

All samples used for these tests were taken from the same length of wire, single conductor number 6 solid, $^6/_{64}$-inch wall of 60 per cent high-voltage rubber compound, tape, and lead sheath. Generator 2 was used with the 1.5x40 wave. Table V gives the test results in volts per mil of wall.

The results in table V indicate no effect of sample length on the impulse strength of the wire, while the 60-cycle strength of the same wire decreases with increasing sample length at about the usual rate. We have seen this unexpected tendency of the impulse strength in other of our test results but plan to investigate it further before accepting it as conclusive. There has been no tendency for the faults in the longer samples to be located near the sample ends. Different arrangements of the longer samples have been tried without finding any consistent effect. Without a cathode-ray oscillograph we have been unable to determine the effect of the sample capacitance on the wave shape, but in view of the results in table II we doubt that this effect is sufficient to affect the impulse strength.

Table V. Impulse Strength of Rubber-Insulated Wire—Effect of Specimen Length

Specimen		Impulse Strength (Volts Per Mil)			60-Cycle Strength (Volts Per Mil)*			Ratio, Impulse to 60 Cycle (Average)
Length (Feet)	Capacitance (μf)	Average	Maximum	Minimum	Average	Maximum	Minimum	
1	0.00006	1,050	1,230	900	580	600	510	1.8
2	0.00012	1,120	1,260	960	550	590	500	2.0
5	0.0003	1,117	1,240	920	496	550	420	2.2
10	0.0006	1,231	1,380	1,020	470	520	430	2.6
20	0.0012	1,130	1,340	920	440	490	400	2.7
40	0.0024	1,128	1,330	925	415	510	380	2.7

* All 60-cycle strengths given in this or other tables are effective and not peak.

The ratios of impulse to 60-cycle strength in table V are seen to be considerably lower than those in table VII because the rather high 60-cycle strength of the table V wire is not accompanied by abnormally high impulse strength. That is, the impulse strength does not seem to have any fixed relation with the 60-cycle strength. On five-foot samples the ratio may vary from two to four.

Impulse Strength of Rubber-Insulated Wire—Effect of Insulation Thickness

These tests were made on five-foot samples of rubber-insulated wire in salt water, using generator 1 with the 1x10 wave. Five samples were tested at each of seven different wall thicknesses between $^5/_{64}$ and $^{22}/_{64}$ inches, on a number 6 conductor or thereabouts. All insulating walls were 60 per cent rubber but of slightly different types. For this reason the actual results gave a rather irregular plot versus wall thickness. The results given in table VI represent a smooth curve averaging the actual results. Therefore, although the reported results are subject to some variation, they represent the trend or general effect of thickness on the impulse strength of 60 per cent rubber insulation on a number 6 conductor.

Table VI. Effect of Wall Thickness on Impulse Strength of Rubber-Insulated Wire

Insulation Wall in 64ths Inch	Impulse Strength in Volts Per Mil
5	1,400
10	1,150
15	970
20	800

In table VI these average results of unit impulse strength decrease with increasing wall thickness. The same tendency has been shown by the a-c strength of many insulations.

Impulse Strength of Rubber-Insulated Wire—Effect of Compound Type

It is well known that there are many different types of rubber cable insulation and that they may differ considerably in their properties. Each type is designed and used for a particular kind of service. The results of table VII are given to show the effect of the rubber compound type on the impulse strength and the ratio between that strength and the 60-cycle dielectric strength.

All samples were five-foot active, number 6 or number 8 with $^5/_{64}$-inch or $^6/_{64}$-inch wall, tested in salt water on generator 2 with the 1.5x40 wave. The results are in volts per mil wall.

The results in table VII indicate at least general correlation between the impulse and 60-cycle strengths. Because of variables in each type of compound that are outside of the present discussion, the impulse and 60-cycle strengths of each type are subject to some variation from the values given. But the results in table VII serve to give the general magnitude and to indicate that the impulse strength of rubber compounds may be as high as 1,600 volts per mil and as low as 700 volts per mil for these insulation walls. In general the impulse strength is seen to be about three times the 60-cycle strength.

Impulse Strength of Rubber-Insulated Tree Wire

These tests were made on generator 2 with the 1.5x40 wave, using five-foot samples of number 6 solid, $^6/_{64}$-inch wall of rubber, braid, with and without fiber tape under the braid, dry and after soaking in water for 20 hours. The dry tests were made with lead foil wrapped over the wire and those after soaking were made in water. Each result given in table VIII is the average of at least five tests on adjacent samples. The 60-cycle tests were made by increasing the voltage three kv per 15 seconds.

The impulse strength of this type of wire is particularly important because the wire is directly exposed to lightning and the insulation wall is seldom more than $^{5}/_{64}$ inch. In table VIII the impulse strength is seen to be generally typical for that rubber wall. The differences between the two types of wire are not enough to indicate that the fiber tape is of any real value as insulation, especially when the wire is wet.

Table IX. Impulse Strength of Cable—Rubber Versus Cambric Versus Paper

Insulation	Impulse Strength (Volts Per Mil)			60-Cycle Strength (Volts Per Mil)			Ratio, Impulse to 60 Cycle (Average)
	Average	Maximum	Minimum	Average	Maximum	Minimum	
Anhydrex rubber	1,143	1,300	900	350	400	310	3.3
Cambric	1,040	1,100	1,000	300	360	250	3.5
Paper	1,920	2,000	1,770	540	570	520	3.6

Table X. Impulse Strength of Sheets—Rubber Versus Cambric Versus Paper

Insulation	Impulse Strength (Volts Per Mil)			60-Cycle Strength (Volts Per Mil)			Ratio, Impulse to 60 Cycle (Average)
	Average	Maximum	Minimum	Average	Maximum	Minimum	
Paper—two layers	3,890	4,400	3,550	1,600*	1,900	1,480	2.4
Cambric—two layers	3,630	4,000	3,200	1,400*	1,590	1,220	2.6
Rubber—one layer	1,993	2,500	1,200	750*	960	600	2.7

Relative Impulse Strength of Rubber, Cambric, and Paper-Insulated Cable

All tests were made on the same size cable, number 6, $^{6}/_{64}$-inch wall insulation, lead sheath. The rubber was a typical 60 per cent, the black varnished cambric was typical of the best available four years ago, and the paper was kraft of about 300 seconds Gurley air resistance saturated with a typical oil used for the solid type of paper cable. Generator 1 was used with the 1x10 wave. The results in volts per mil wall are given in table IX.

Table VII. Impulse Strength of Different Rubber Compounds

Compound	Impulse Strength (Volts Per Mil)			60-Cycle Strength (Volts Per Mil)			Ratio, Impulse to 60 Cycle (Average)
	Average	Maximum	Minimum	Average	Maximum	Minimum	
Code	880	920	840	315	320	310	2.8
AO	870	990	690	255	260	250	3.4
Ozone resistant	1,090	1,290	920	359	400	290	3.0
Performite	740	830	700	275	280	270	2.7
AA-35	840	970	700	347	360	320	2.5
60 per cent S. C.	1,137	1,500	710	375	450	300	3.0
60 per cent H. V.	1,600	1,665	1,535	470	510	430	3.4
Anhydrex	1,340	1,460	1,360	338	365	320	4.0

Table VIII. Impulse Strength of Rubber-Insulated Tree Wire

	Average Impulse Strength				Average Wet 60-Cycle Strength		Wet Ratio, Impulse to 60 Cycle
	Dry		Wet				
	Kv	Volts Per Mil	Kv	Volts Per Mil	Kv	Volts Per Mil	
Fiber tape	107	1,370	89	1,140	24.4	313	3.6
No fiber tape	96	1,230	86	1,100	22.3	286	3.8

The impulse strength of the paper is nearly double that of the rubber and cambric but it is interesting to note that here again as in table VII there is good correlation between impulse and 60-cycle strength. The insulations of high 60-cycle strength show correspondingly high impulse strength.

Although the impulse strength of the rubber in table IX is 40 per cent less than that of the paper, one of the rubber compounds in table VII is only 17 per cent less than the paper in table IX. Since the 60-cycle strength of the best rubber compound in table VII does not represent the highest obtainable with rubber, this suggests that it might be possible to make rubber compounds that are equal to paper in impulse strength. Because of the compounding variables the dielectric strength of rubber is subject to control over a much wider range than that of either cambric or paper.

Impulse Strength of Rubber, Cambric, and Paper Sheets

All tests were made between two-inch-diameter brass electrodes with rounded edges, using generator 1 with the 1x10 wave. The paper was kraft of about 2,000 seconds Gurley air resistance, in layers of 0.005 inch, saturated in paper-cable oil. The varnished cambric was in 0.012-inch layers of the same type as that in table IX. The rubber was 60 per cent in 0.050-inch layers. The test results in volts per mil are given in table X.

As would be expected these results are seen to be considerably higher than those on the insulations in cable form. The strength of the sheet rubber is some 50 per cent higher than that of the thinner rubber cables tested. Similar to the cable insulation the paper sheet strength is about double that of the rubber sheet, but unlike the cable insulation the sheet cambric strength is nearly as high as the paper sheet. On sheets the ratio of the impulse strength to the 60-cycle strength is seen to be about 2.6.

Properties of Impulse Faults in Rubber and Cambric Insulation

The above results indicate that in most cases the impulse strength of rubber is in general as high as that of cambric. This does not agree with our general experience that rubber is somewhat more subject to lightning damage in service than is cambric. For this reason we made a few comparisons of the proper-

Table XI. Properties of Impulse Faults in Rubber and Cambric Insulation

	Rubber Sample	Cambric Sample
Sample 1		
15 kv d-c for 15 min.	OK	OK
165-kv impulse	Failure	Failure
3 kv a-c for $1^{1}/_{2}$ hours	OK	OK
D-c dielectric strength* (kv)	6.2	10.1
A-c dielectric strength (kv)	3.8	5.2
Sample 2		
165-kv impulse	Failure	Failure
A-c dielectric strength (kv)	4.3	5.8
Sample 3		
A-c dielectric strength (kv)	45 (480 volts per mil)	31 (290 volts per mil)

* One-fifth-ampere fuse.

Table XII. Low-Energy Impulse Faults in Rubber

Sample 1

Impulse failure at 70 kv. No flash but glass broken
No location with magnifying glass
OK on 1,000-volt Megger
Fault picked up at 4 kv d-c by 0.6-milliampere kenotron
Fault less than 0.5 millimeter in diameter

Sample 2

Impulse failure at 60 kv
Fault located to within two inches by aid of flash
No location with magnifying glass
Fault picked up at 3.4 kv d-c by 0.6-milliampere kenotron
Fault less than 0.1 millimeter in diameter

ties of these faults in the two types of insulation.

The tests reported in table XI were made on two-foot samples of number 6 solid, $^{6}/_{64}$-inch wall of insulation lead sheath. The impulse tests were made on generator 1 with the 1x10 wave.

As shown in table XI both number 1 samples withstood 15 kv direct current for 15 minutes without failure but failed when subjected to a 165-kv impulse. After this both samples withstood 3 kv alternating current for 1.5 hours without failure, when they were removed from test. Since this voltage is more than double the operating voltage of each cable it shows that both faults would have remained in service for a considerable period after the impulse failure. Finally each fault was broken down with direct current. Although this test was made with a one-fifth-ampere fuse in series with the sample each fault was burned out to some extent. In spite of this burning each fault showed an a-c strength more than twice the operating voltage. It is interesting to note that the cambric fault gave considerably higher dielectric strength on both the d-c and a-c breakdown tests. That is, both faults would have withstood the operating voltage for some time after the impulse failure, possibly indefinitely, but the cambric fault was less likely to cause a service failure than the rubber fault. The tests on the number 2 samples confirm this comparison.

This indicates that an impulse fault in cambric is less likely to cause a service failure than one in rubber but that in either insulation the impulse failure may not cause a service failure for days, months, or even years after the impulse failure. In confirmation of this we have found lightning faults in rubber-insulated cable that was taken from service after a perfect operating record. The presence of water undoubtedly would increase the probability of an impulse fault failing in service; that is, the cable may fail during the first rainstorm after the lightning, or it may never fail.

Incidentally, these tests bring out one advantage of high-voltage d-c testing. It is a most effective means of developing any lightning faults that may be in the cable.

Table XII gives additional data to indicate the small size of a low-energy impulse fault. Each sample was one foot of number 1 4,$^{3}/_{64}$-inch wall of rubber, tested under water in a glass jar, using generator 1 and the 1x10 wave.

The results show that the size of such a fault may be extremely small, too small to be visible on the outside surface of the rubber. Even after being burned out by the kenotron the faults were very difficult to locate visually.

Conclusions

Within the limits of the tests made, the following conclusions appear justifiable:

1. The impuse strength of cable insulation is not critically affected by the shape or polarity of the impulse, the type of outer electrode, or the length of the specimen.

2. In walls of $^{6}/_{64}$ inch or thereabouts the impulse strength of rubber-insulated cable may be from 700 to 1,600 volts per mil depending on the type of rubber compound. The strength decreases with increasing wall.

3. The impulse strengths of varnished-cambric and oil-paper insulated cables are about 1,000 and 2,000 volts per mil respectively.

4. The impulse strength of cambric and oil paper insulated cable is between three and four times the 60-cycle strength but that of rubber-insulated cable may be anything from two to four times the 60-cycle strength.

5. In sheets between two-inch disks the impulse strength of rubber is some 50 per cent higher than that of rubber cable insulation of the same wall. Similar to cable insulation the sheet paper is about double the sheet rubber but unlike cable insulation the sheet cambric is nearly as high as the paper.

6. The fiber tape and braid in rubber-insulated tree wire do not add appreciably to the dielectric strength impulse or 60 cycles of the wire, particularly when wet.

7. An impulse fault in cambric insulation has higher a-c strength than one in rubber insulation but the a-c strength of either fault may be sufficient to withstand the operating voltage for long periods of time.

Discussion

R. B. McKinley (nonmember; General Electric Company, Schenectady, N. Y.): We have also made some impulse tests on rubber insulation. Most of these were on 30 per cent and ozone-resisting compounds.

Our test results were in agreement with those presented by Messrs. Davis and Eddy in the fact that the impulse strength in volts per mil decrease rather rapidly with increasing wall thickness. Some of the answer for this might be due to the mechanics of manufacture in that it is more difficult to hold the heavy insulation walls perfectly centered during the vulcanization period, although this was checked carefully and the fact that there might be greater difference in the degree of "cure" throughout the insulation wall. That the degree of vulcanization does have some effect is indicated by a few tests we have made.

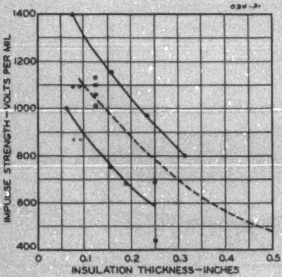

Figure 1

Our values, together with some of those reported in the Davis and Eddy paper, have been plotted, and I believe the chart is worthy of a little study, as it might offer an additional reason why general experience indicates that rubber is more subject to lightning damage than varnished cambric. Furthermore, it might also indicate the advisability of further study before adopting rubber insulation for voltages in the range from 22 to 35 kv in places exposed to severe surges.

The upper curve of figure 1 of this discussion was drawn from values given in table VI of the Davis and Eddy paper. The lower solid curve shows our results obtained on 30 per cent insulation. It is interesting to note how closely the two curves parallel each other throughout the range of thicknesses tested. The points marked by crosses were taken from table VII for 30 per cent class *AO* rubber and indicate how closely the tests agree.

The points indicated by circles or squares are those for the ozone-resisting or oil-base compounds, including insulations of various manufacturers. I have drawn the dotted curve in parallel to the other two curves and extrapolated to one-half-inch insulation thickness merely to investigate what the possibilities might be at the higher voltages. The true curve for ozone-resisting insulations might of course be much different from the dotted curves shown, although the small amount of information that we do have does indicate that these insulations also have lowered impulse strength with increased thickness.

I have calculated the breakdown voltages for 26-kv cable with varnished cambric, paper, and oil-base insulations. The thicknesses of insulation for 26-kv grounded neutral for the three insulations would be 0.422 inch, 0.297 inch, and 0.469 inch, respectively. Using 1,040 volts per mil for the varnished-cambric insulation in accordance with the Davis and Eddy results, 1,600 volts per mil in accordance with the Foust and Scott paper, and 500 volts for the oil-base insulation as indicated by the extrapolated curve, the following values would be obtained:

Varnished cambric	439 kv
Paper	475 kv
Ozone-resisting	235 kv

I do not want to leave the impression that I am saying rubber insulation will not operate at 26 kv. There are cases in service to disprove that, but I do believe the results given in this paper show us something that bears looking into further before we extend the use of high-voltage rubber too rapidly.

C. M. Foust (General Electric Company, Schenectady, N. Y.): The work reported by Messrs. Davis and Eddy is interesting and valuable. On several occasions I have conducted similar tests on impulse breakdown strength of rubber insulation and have reached conclusions in agreement with the authors on most points. My general level of voltages and gradients for various wall thicknesses agrees with the figures given in the several tables of the paper and breakdown gradients decreased with increasing thicknesses as shown in table VI.

I am puzzled by the results shown in table V on the effect of specimen length. In view of the variation in breakdown between samples at any one specimen length, it seems reasonable that the impulse strength for the longer specimens should decrease as the 60-cycle values do. It is a little disconcerting to have the impulse 60-cycle breakdown ratio vary with specimen length. I am wondering if in some of the tests described an appreciable portion of the output voltage of the generator might not have been across the ground-electrode water resistance, particularly for the longer test pieces of high capacitance. At a breakdown voltage of 90 kv reached uniformly in one microsecond across a capacitance of 0.0024 microfarad, the current through the water would be about 200 amperes. At anything less than, say, ten ohms, this would be inconsequential. However, at higher resistances an appreciable resistance voltage would be obtained, resulting in reduced voltage across the insulation particularly for breakdown values occurring before crest.

Our tests using the cathode-ray oscillograph with the viewing and recording each applied wave showed breakdown to be occurring before or on the wave crest. In many cases final breakdown indicated by the chopping of the wave, occurred substantially below the previously applied crest-voltage level and on the rising front. When these actual chopped wave values are taken a breakdown-voltage value some ten per cent below the full-wave value is obtained.

In my test only one voltage wave was applied at each level while the authors applied two. Indications of occasional damage without breakdown suggest that some five applications at each level would provide a more representative breakdown value.

The authors have described tests wherein successive applications of direct, impulse, and direct voltage were applied with the conclusions derived therefrom that a cable having an impulse breakdown may remain in service for some time. However, in service the normal excitation would usually be on at the time of impulse failure and immediate follow-up of short-circuit current would certainly result in many cases.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): Information on the surge breakdown strength of insulated power cables has been rather meager, and so the data on a variety of insulations from Davis and Eddy and on impregnated-paper insulation from Foust and Scott are quite welcome. In general, data on surge strengths of various insulations have been appearing in relatively good quantity in recent years in this country and abroad, particularly at the Paris meetings of the International High-Tension Conference.

Troubles in cables due to lightning have been pretty much confined to the lower-voltage cables connected to overhead systems. Dielectric strength to withstand surges, either due to switching or due to lightning, may, however, be the limiting factor in determining minimum safe insulation thicknesses for the higher types of insulation in extra-high-voltage cable. Surge strength to withstand switching surges was a factor, for example, when in Chicago we adopted, in 1935, oil-filled insulation of 315 mils thickness for the 100,000-kva 66-kv lines, whereas with the solid-type 66-kv cable with about 688 mils of insulation the surge strength was greatly in excess of requirements.

The industry would, I believe, be interested in data obtained by others similar to the data on a number of variables obtained by Davis and Eddy, since such data are comparatively rare.

The rest of this discussion applies to impregnated-paper insulation for particularly power cables.

The average surge strength of 1,600 volts per mil found by Foust and Scott agrees reasonably well with the results of Held and Leichsenring[1] who reported 1,770 to 2,400 volts per mil average surge breakdown stress and with the average value of 1,920 volts per mil given in the paper by Davis and Eddy presented at this convention.

Some discrepancies between the results of various investigators probably are due to the effects of different variables which have not been well established as yet. It appears, for example, that higher breakdown values are obtained with small laboratory samples than with complete cables. It is gratifying, therefore, that the tests reported in the Foust-Scott paper were all made on complete cables. In a 1933 AIEE paper, Mr. Scott reported the results of surge tests on 15 mils of impregnated-paper insulation between flat electrodes. The surge strength for these samples was about 3,400 volts per mil. J. Borel[2] reported last year results of surge tests on small laboratory samples with concentric electrodes and insulation thicknesses of 40 to 160 mils. He obtained surge breakdowns at a maximum stress of about 2,900 volts per mil and an average stress of about 2,500 volts per mil. Also the results of Davis and Eddy confirm the conclusion that much higher surge strength values are obtained for small laboratory samples than for complete cables. They report for the former an average impulse strength of 3,890 volts per mil as compared with 1,920 volts per mil for the complete cables.

The relative surge strength of various types of cable still seems somewhat indefinite, even after considering the two papers. In a paper by Buss and Vogel,[3] published in 1935, the following tentative values were given: solid-type cable, 2,540 volts per mil; oil-filled cable, 2,000 to 2,540 volts per mil; pressure cable, 2,540 to 3,000 volts per mil. While these results indicate higher surge strength of pressure cable than for solid-type or oil-filled cables, Mr. Scott stated in his 1933 AIEE paper that "at power frequencies and under long time application of voltage there is a considerable increase in endurance strength of oil-treated insulation at pressures of several atmospheres. Under impulse stresses, however, practically no benefit is derived from increasing pressure. The effect of pressure on dielectric strength is greater the longer the time of voltage application, being negligible for the impulse voltage tests of only a few microseconds duration." On the other hand, Borel found an increase in surge strength with increasing pressure.

Other questions of interest are the effect of thoroughness of impregnation and of aging on the surge strength of cables, the cumulative effect, if any, of repeated surges, the surge strength of three-conductor belted cables as compared with single-conductor cables, and the shape of the time-lag curve. It is realized that tests of this type are cumbersome, and progress in answering these questions will be of necessity slow.

It is noted that all tests were made by Foust and Scott with positive polarity and most tests by Davis and Eddy were with negative polarity. Held and Leichsenring found no effect of the polarity on oil-filled cables but for solid-type cables obtained 5 to 13 per cent higher surge strength for positive waves than for negative waves. The higher lightning voltages are usually negative.

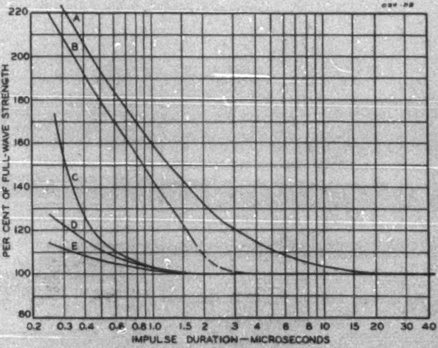
P. L. Bellaschi and **W. L. Teague** (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): These papers by Foust and Scott and Davis and Eddy present interesting data on the impulse and 60-cycle strength of insulating materials particularly those used in cables. In testing similar materials and parts and in our experience with the various factors affecting insulation breakdown, we have obtained results which are, on the whole and in principle, in accordance with the findings so ably reported in the papers by Messrs. Davis and Eddy and by Messrs. Foust and Scott. It would lead the discussion too far afield with perhaps no particular profit to attempt a minute comparison of the various findings.

There is a pertinent point which has a practical and a fundamental bearing on the insulation problem. Both papers indicate a volt-time characteristic for the type of insulation tested which is essentially constant down to one or two microseconds. These are in effect the shortest times to which the investigations were carried. The curves of figure 2 of this discussion enlarge on this fundamental question. These curves present the volt-time characteristics of liquid and solid insulation, and of apparatus insulation from the long times down to the very short impulses of 0.25-microsecond duration.

Curve *A* is the characteristic for transformer oil between a disk and a plate; curve *D* is for oil impregnated pressboard for the same electrode arrangement.[1] Curve *B* is the volt-time characteristic of major transformer insulation as applied to high-voltage design.[2] Curve *E* is for turn-to-turn oil-impregnated paper insulation. Curves *D* and *E* are also typical for other insulation, as varnished cloth, etc. While we have no data at this moment on the impulse characteristic for rubber at the very short times, there are no good reasons to suspect that it has a greater upturn at the very short times than in these last two curves.

The degree of the upturn of the volt-time characteristic depends on a number of factors, as the relative amount of liquid and solid insulation which make up the insulation body or structure, the treatment applied to the insulation, the electrode arrangement and insulation of the electrode proper, etc.

Figure 2. Volt-time characteristics of insulation



A—Transformer oil, one-fourth inch between disk and plate electrodes (reference 1)
B—Transformer major insulation (reference 2)
C—Oil-filled cables (reference 3)
D—Oil-impregnated pressboard. Average for $^1/_{16}$- and $^1/_8$-inch thickness between disk and plate electrodes (reference 1)
E—Oil-impregnated turn-to-turn insulation. Average values for 0.03-, 0.06-, and 0.12-inch thick paper

Curves *A*, *D*, and *E* apply for repeated applications, which consist usually from 15 to 30 impulses being applied before the point of breakdown is reached. Curve *B* is an endurance curve for hundreds of applications.

Curve *C* (from the test data on cables by Held and Leichsenring) was established from single applications. On the flat part, repeated applications gave voltage values not more than five to ten per cent lower. It is possible that the upturn at the very short times would be lower on repeated applications and that the curve would come nearer to *D*. There are, however, other factors which may account for the substantial upturn of curve *C*, as the presence of oil in relatively good amount in an oil cable. The results of Held and Leichsenring at the longer times apparently differ in one respect from those of Messrs. Foust and Scott, in that the former found the breakdown gradient at the conductor to be a constant.

The additional data on the dielectric strength of cable insulating materials, presented in these two papers, should make it possible to better tie in the relative strength and characteristics of various apparatus, and to this additional extent, give further scope and strength to the general problem of insulation co-ordination.

L. G. Smith (Consolidated Gas Electric Light and Power Company of Baltimore, Baltimore, Md.): The industry is indebted to the authors for the data contained in the papers by Foust and Scott and Davis and Eddy. We have impulse flashover strength of line and station insulators and have available impulse levels of transformers and other apparatus. These data for cable augment the information necessary to design the system insulation levels and lightning protection installations. The impulse breakdown values reported presumably are for new cable. While information for new insulation is a necessary step, the user is also interested in similar data for older cable, after voids have formed, the oil deteriorated, or some "tracking" has occurred in paper cable; the rubber has aged in rubber-insulated cable; or the insulation has deteriorated in varnished-cambric cable. Lightning protection must be designed to protect the cable throughout its useful life. It is realized that obtaining the data presented in the papers involved considerable time and expense; and that the testing necessary to establish impulse strength of insulation as it ages represents even greater costs. However, the suggestion is made at this time as a guide to further research.

In interpreting the data on paper cable, the conclusion is reached that insulation thickness and conductor size has slight effect upon the impulse strength. On the other hand, the insulation thickness appears to have a material effect upon the impulse breakdown of rubber cable. It would be of value to determine the effect of conductor size on both rubber and varnished-cambric insulated cable and the effect of insulation thickness on varnished cambric cable.

It is interesting to note that the type of rubber compound that supposedly possesses the best aging characteristics developed the lowest impulse breakdown. The statement made in the Davis and Eddy paper that an impulse breakdown of rubber or varnished-cambric insulated cable may not result in a service failure is questioned. The 60-cycle tests were made subsequent to impulse breakdown. If normal rated 60-cycle potential had been connected to the cable at the time of the impulse test, it is believed that power follow current would have reduced the fault resistance to the point where normal voltage could not have been withstood.

L. F. Hickernell (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): This paper is a valuable contribution to the knowledge of the electrical characteristics of insulated power cables in that it presents, for the first time before the AIEE, impulse-strength data on varnished-cambric and rubber cable insulation. Previous and accompanying papers have been confined to similar data on impregnated-paper insulation. ("Traveling-Wave Voltages in Cables" by H. G. Brinton, F. H. Buller, and W. J. Rudge, AIEE Transactions, March 1933, page 121, figure 7, and "Some Impulse-Voltage Breakdown Tests on Oil-Treated Paper-Insulated Cables" by C. M. Foust and J. A. Scott, AIEE Transactions, volume 59, 1940, pages 389–91.)

Impulse Generators

Referring to "Impulse Generators", it is stated the *impulse* voltage was applied in seven-kv steps. Referring to "Impulse Strength of Rubber-Insulated Tree Wire", it is stated that the *60-cycle* voltage was applied at the rate of three-kv per 15 seconds. In determining values of ultimate breakdown strength, the rate of rise of the applied voltage is important. Generally speaking, the faster the rate, the higher the value obtained. Accordingly, the following questions arise:

1. Were all 60-cycle breakdown tests conducted with the same rate of rise of applied voltage?
2. If so, what was the rate? (That is, does the three-kv per 15 seconds, stated under "tree wire" apply to *all* 60-cycle tests?)

If the rate of rise were three-kv per 15 seconds, it should be noted that the values in the paper cannot directly be compared with data obtained from factory test reports which generally are governed by ASTM designation *D*470-37*T*. Section 13 of this standard specifies a rate of rise of three-kv per second.

Effect of Electrode Surface on Impulse Strength

Table IV shows the results obtained with the following means of providing the grounded electrode:

1. Lead sheath
2. Immersion in salt water
3. Lead foil wrapped over insulation

It is concluded that the method used has no effect on the results. Inasmuch as (1) is unaffected by the time of immersion whereas (2) and (3) are, it would seem that the time of immersion prior to test was relatively short and should be so stated. In any event, the limit of the time of immersion for which this conclusion holds should be stated.

Effect of Insulation Thickness on Impulse Strength

Table VI indicates a decrease in unit impulse strength with increasing wall thickness which is the basis for the statement, "The same tendency has been shown by the a-c strength of many insulations." While it is generally true that the unit *60-cycle* strength decreases with increasing thickness, most investigators have found that the unit *impulse* strength of insulations in general is practically proportional to their thickness; or as popularly stated, "an inch is an inch" insofar as impulse strength is concerned. This has been demonstrated by many investigators for porcelain insulators and to a more limited extent for impregnated-paper insulation (see references in first paragraph). Therefore, it would seem that if the data in table VI are truly representative after confirmation, the conclusion should be confined to *rubber* insulation.

Effect of Compound Type on Impulse Strength

In table VII, the following average 60-cycle strengths are shown for three types of rubber insulation:

Rubber Compound	60-Cycle Strength (Average) Volts Per Mil
Code	315
ASTM type *AO*	255
Performite	275

While no claim has been made generally that type *AO* or Performite are high-voltage insulations, it is rather surprising to note that the authors obtain lower dielectric strength with their type *AO* (30 per cent) and Performite (35 per cent) than they do on their Code (20 per cent) compounds. It

Table I

Table Number	Insulation	Conductor (American Wire Gauge)	Insulation (64ths)	Outer Electrode	Impulse (Average Volts Per Mill)
VII	Anhydrex	6 or 8	5 or 6	(Salt water)	1,340
IX	Anhydrex	6	5	Lead	1,143
				Ratio =	1.17

is not believed that this is truly representative of the relative rating of these types of insulations in the industry in general.

RELATIVE IMPULSE STRENGTH OF RUBBER, CAMBRIC, AND PAPER-INSULATED CABLE

Rubber. The text states these tests were conducted on a "typical 60 per cent rubber," table IX indicating this to be "Anhydrex" rubber. It would be interesting to know the reason for the lower impulse strength of Anhydrex rubber shown in table IX as compared with table VII, as shown in table I of this discussion.

Paper. It would be of interest to know the thickness of the paper tapes as well as the Gurley air resistance. It may be pointed out that 300 seconds air represents a *low* density paper as judged by modern standards of paper-cable manufacture. This paper is quite different from that used for the sheet tests reported under "Impulse Strength of Rubber, Cambric, and Paper Sheets" (five mils, 2,000 seconds Gurley).

The term "typical oil" is rather indefinite in view of the present use of naphthenic and paraffinic-base oils from different fields, with or without rosin, by the several manufacturers.

Control of Rubber. The authors suggest the possibility of making rubber insulation equal to paper in impulse strength because the "compounding variables" in rubber are subject to a wider range of control than in paper or cambric. In this endeavor, the well wishes of the entire industry will be extended to them. However, it would seem only fair to point out that both theory and present experience would indicate this to be a most difficult if not impossible assignment. In general, dielectric strength seems to follow the same laws as mechanical strength; namely, a laminated structure is stronger than a solid structure. Rubber is a more or less solid material; paper and cambric are laminated structures.

While it is true that there are more "compounding variables" in rubber than paper and cambric and hence more factors to juggle, there are also more chances for things to go wrong and the manufacture is on the whole less subject to control. A recipe for a rubber insulation will contain from five to ten ingredients compared with two for paper or cambric. The advantage of this flexibility is offset by the difficulty of controlling the quality and dispersion of so many ingredients (gum rubber itself is practically impossible to control). In addition to formulation, a rubber compound must be mixed, rested, warmed, tubed or stripped, and vulcanized. While these operations are subject to some control, the degree does not approach that capable with paper insulation. A paper cable can be closely governed by actual measurement of its electrical characteristics during its processing. Accordingly, it is doubtful if a commercial length of rubber cable can be made foot by foot of as high and uniform quality as paper cable simply because the manufacturing processes are inherently not subject to as fine a degree of control.

PROPERTIES OF IMPULSE FAULTS IN RUBBER AND CAMBRIC INSULATION

The conclusion that the 60-cycle strength of either rubber or cambric is sufficiently high after an impulse fault to prevent a *service* failure for some time is not substantiated by the test data in table XI. In actual service, a lightning fault is generally followed by a 60-cycle power arc which burns the insulation and greatly lowers the a-c strength. This service condition is not simulated in a shot from an impulse generator with no power follow-up.

E. W. Davis and W. N. Eddy: Mr. McKinley's calculated comparison of the impulse strength of 26-kv walls of varnished cambric, paper, and rubber leaves the rubber a poor third with only one-half the impulse strength of paper or cambric. We cannot agree that this comparison is justifiable, for three reasons:

1. His determination of the ozone-resistant rubber strength by extrapolation to 0.469-inch wall is too speculative with the available data limited to six points between 0.075- and 0.125-inch wall.

2. His assumption that the cambric strength at 0.422-inch wall is as high as that at 0.094-inch wall does not appear justified in the complete absence of data. Cambric may not be any more similar to paper in impulse strength than in other electrical properties.

3. For a 26-kv cable we would use a 60 per cent high-voltage rubber (with proper ozone protection) which in table VII has an impulse strength 50 per cent higher than that of the ozone-resistant rubber.

Both Mr. Foust and Mr. Hickernell question the significance of the data in table XI because the impulse faults were not produced with the 60-cycle and impulse voltages superposed as they probably would be in the field. We do not believe that this limitation is serious. Considerable data from laboratory tests on cable taken from service, from field tests on installed cable, and from customers' records indicate that impulse faults may be formed in the presence of continuously applied 60-cycle voltage and the cable still remain in service for an indefinite period after the lightning damage. A typical field experience is that the breaker opens during the storm but is immediately reclosed with no further trouble. Sometimes there is not even this indication of lightning trouble. Hours or even days after the storm the cable fails. Subsequent tests show that in addition to the developed fault causing the failure the cable often contains other faults having properties very similar to the laboratory-made impulse faults described in tables XI and XII.

Mr. Foust is puzzled by the constant impulse strength shown in table V with increasing sample length. We share his point of view. In fact we investigated the matter in more detail than is indicated in the paper and intend to continue this investigation at the first opportunity. In connection with his discussion of the voltage drop across the water the following testing details lead us to doubt that an appreciable portion of the impulse is taken by the outer cable electrode.

All water was salt water. Tests were made in water on samples from one length at one, two, five, and ten feet from another length at one, two, five, and ten feet and from another length at two and five feet. Tests were made on leaded samples (not in water) from another length at 10, 20, and 40 feet. None of these 70 tests show any appreciable effect of the length. They are all well represented by the values in table V.

With reference to Mr. Hickernell's questions, in the order given;

1. All 60-cycle breakdown tests were made with the same rate of voltage increase, three kv per 15 seconds. Our experience indicates this rate to be the most practicable in general for such purposes. We have been using it more than 12 years.

2. In connection with table IV we do not understand his statement that method 3 (lead foil wrapped over insulation) is affected by the time of immersion. Only method 2 (immersion in salt water) is affected by the time of immersion. In general our tests indicate that there is no appreciable influence of immersion time in salt water on dielectric strength for several months. Since none of the samples reported in the paper were immersed in the salt water more than one hour, we believe there is no influence of immersion time.

3. We agree that any conclusion from table VI should be limited to rubber insulation. In fact we feel that the wording of the paper makes this quite obvious.

4. With reference to table VII he questions the relative 60-cycle strengths of Code, *AO*, and Performite compounds (given as 315, 255, and 275 volts per mil respectively). Our tests indicate that these differences in dielectric strength are too small to be of any significance. These particular values were obtained on the particular wire used for the impulse tests. Hundreds of other tests made by us on these three compounds indicate no significant difference in 60-cycle strength among the three of them.

5. He questions the slight difference in the impulse strengths of Anhydrex shown in tables VII and IX. We have a good many different Anhydrex compounds. As it happens, that in table IX showing a strength of 1,143 volts per mil is one of the earlier compounds while that in table VII (1,340 volts per mil) is a more recent compound. As stated in the paper, all the tests were not made at the same time.

7. The tapes in the paper cable were three-fourths inch wide by 0.007 inch thick. The oil was paraffin-base, without rosin.

8. Without attempting a detailed discussion of the control of rubber we may say that we are unable to share Mr. Hickernell's pessimism in this respect, because we have too much evidence that the physical and electrical properties of rubber compounds can be kept under close control.

Co-ordination of Power and Communication Circuits for Low-Frequency Induction

J. O'R. COLEMAN
MEMBER AIEE

H. M. TRUEBLOOD
MEMBER AIEE

WHERE power and communication facilities are in proximity, electromagnetic induction from the power system may cause disturbances in the communication system. The avoidance or minimizing of such disturbances, with due regard to the service and other needs of both systems, is a problem of co-ordination, which is conveniently divided into two parts, one dealing with low-frequency inductive co-ordination and the other with noise-frequency co-ordination.

The present paper undertakes a general examination of the problem of low-frequency inductive co-ordination in the light of developments during the past decade. The situation as it existed at the beginning of the decade is to be found well set forth in a paper presented in 1931 at the AIEE winter convention by R. N. Conwell and H. S. Warren. The present paper, like its predecessor, derives from the work of the Joint Subcommittee on Development and Research[*] of the Edison Electric Institute and the Bell System. It is largely concerned with induction from currents due to power system ground faults and the transients which accompany such faults. It gives relatively little attention to continuous low-frequency effects since, up to the present at least, such effects have not been a primary concern in the low-frequency co-ordination of commercial power circuits and Bell System communication circuits.

A further object of the paper is to outline the various factors that require consideration in practical situations and to discuss their significance under present-day conditions. To provide necessary background for this, recapitulations of fundamentals are included at appropriate points. Detailed discussions necessarily omitted from the paper itself are to be found in the papers listed in the bibliography, many of which, particularly the Conwell-Warren paper,[1] contain further references.

A situation which calls for measures of inductive co-ordination ordinarily involves a parallelism or quasi parallelism of sections of power and communication lines. The possibility of disturbance by electromagnetic induction from the one system to the other depends upon certain characteristics of the power system (called "influence factors") and also upon such characteristics of the communication system as affect its liability to disturbance ("susceptiveness factors"). Of equal significance are the "coupling factors", which determine the electromagnetic coupling between the two systems. Figure 1 is a diagrammatic representation of the main factors of these three groups in a low-frequency induction situation. Some of these items can obviously be evaluated by calculation or by relatively simple tests, while others do not lend themselves to determination by such methods.

In a low-frequency induction problem, where, as in figure 1, power-system ground-faults are involved, it is customary, first, to calculate the maximum "open-circuit" longitudinal induced voltage. To do this, values are required for the residual power current (that is, in general, ground-return current) to produce this maximum voltage and for the corresponding coupling coefficient. The "open-circuit" voltage thus calculated is next reduced to what may be called the "shielded" maximum longitudinal induced voltage. In this reduction, allowance is made for shielding effects exerted by normally grounded paralleling conductors (ground wires, cable sheaths, etc.) and, in the case of cables, by core conductors. In addition, allowance must be made for additional shielding resulting from longitudinal currents set up in communication conductors normally free from connections to ground, but which become grounded, through protector operation, as a result of the induction. This latter allowance is not ordinarily a simple matter.

It is also usually necessary to know approximately how frequently voltages within specified ranges of magnitude will be induced, and how long they will last when they occur, since the duration of the disturbance affects the energy transferred to the communication system.

Further, although the longitudinal voltages are determining with respect to some kinds of interference, voltages to ground are important with respect to other types. Hence a certain amount of estimating of the distribution of the induced longitudinal voltages with respect to ground is generally desirable.

The final step is, of course, the estimation of the adverse effects of these voltages upon the operation and maintenance of the communication circuits, and the determination where necessary of measures to be taken in either or both systems to minimize the effects.

Valuable information regarding the fundamental factors just discussed has been secured in an analysis[2] of automatic oscillograph observations from 29 actual exposures, which also indicated sources of uncertainty in making advance appraisals of low-frequency induction situations. Comparison of maximum observed voltages with maximum estimated values showed deviations up to about 75 per cent, in both directions. Contributing to these discrepancies were shielding from telephone-line conductors grounded by protector operation, erroneous assumptions of fault resistances, failure of faults to occur at or near locations to produce the maximum voltage, and wave-shape distortion of induced voltage. Duration of induced voltage, distance between protector locations, and number of wires on the telephone line were important in cases of protector grounding. Distribution of induced longitudinal voltage with respect to ground was clearly a matter of importance, although not covered by the available data.

The several factors of influence, coupling, and susceptiveness will now be discussed in order.

Power Systems—Influence Factors

RESIDUAL CURRENT MAGNITUDES—CALCULATION AND LIMITATION

The magnitude of fault current and its distribution among the various branches of a network may be calculated for any

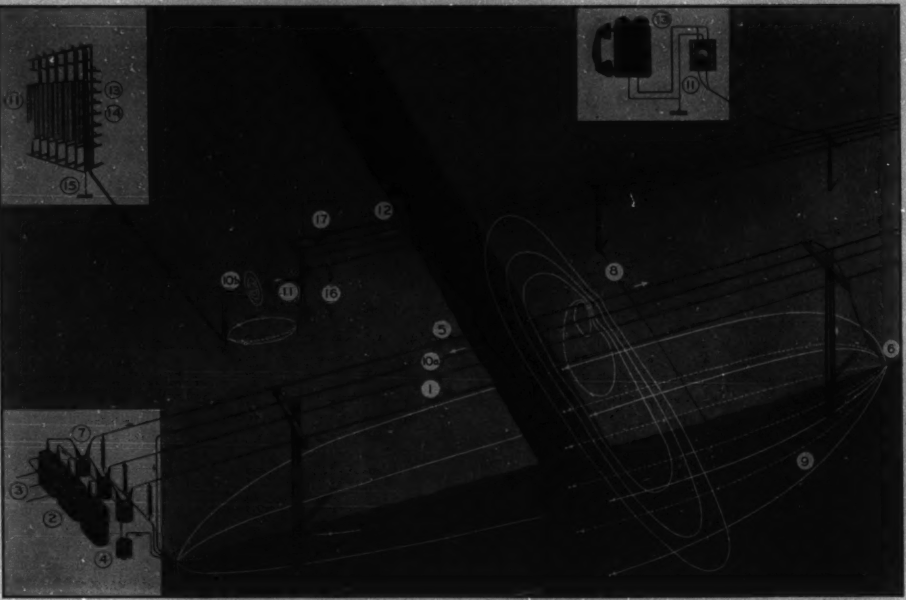

Figure 1. Factors affecting the severity of an inductive exposure

Influence Factors—Affecting magnitude and duration of power-system residual fault current:

1. Line voltage
2. Transformer impedance
3. Impedance of supply to transformers
4. Method of neutral grounding and grounding impedance if used
5. Power-line impedance
6. Fault location and fault resistance
7. Circuit breakers and tripping equipment

Factors (not indicated in drawing) affecting frequency of occurrence in faults include:

Lightning, wind, and sleet storms
Construction practices
Foreign objects in line

Coupling and Shielding Factors—Affecting induced voltage in communication system for given residual current in power system:

8. Separation between lines
9. Earth resistivity (also affects influence)

10a, 10b. Shielding from power-line ground wire and telephone-cable sheath when present

Susceptiveness Factors—Affecting communication system disturbances under given induced-voltage conditions:

11. Protectors—breakdown of blocks and rating of fuses
12. Size, length, kind, and number of wires on line (Some wires may become shielding conductors due to protector-block operation)
13. Low-frequency characteristics of equipment
14. Impedance to ground of terminal equipment
15. Resistance of ground connection
16. Voltage from conductors to ground
17. Voltage between wires (arising from differences of voltage to ground)

(Not indicated)—Location of exposure with respect to nearest protector blocks

assumed fault location and operating setup.[3] For a grounded-neutral system the fault location is usually assumed at the end of the exposure remote from the neutral ground. When line-to-ground fault current may be fed into the exposure from two directions, consideration should be given to the sequence of breaker operation in calculating the conditions for maximum induced voltage. Where ungrounded circuits are involved, it is the usual practice to assume a fault on one phase at one end of an exposure and a fault on another phase at the other end. This condition gives the maximum possible ground current through the exposure and hence the maximum induced voltage. As a rule, this current is larger than the current through the same exposure under the assumption of direct-grounded power neutral.

The impedances of power lines and cables are important elements in determining the magnitudes of residual currents under fault conditions. The most important gaps of ten years ago in data regarding these quantities have been filled in a report of the Joint D. & R. Subcommittee.[4] Impedances in power-circuit neutral-ground connections of course affect ground-fault current magnitudes. Such impedance may be inherent in the grounding equipment or may take the form of an external resistor or reactor, or a Petersen coil (ground-fault neutralizer). Considerations arising from power system design and operation affect the magnitude of neutral impedance which may be used.

In calculating ground-fault currents for use in estimates of induced voltages, significant errors may be caused by failing to take account of fault resistance. This, and other fault characteristics of interest, have been studied by the Joint D. & R. Subcommittee with the co-operation of a number of power companies.[5,6] Data were collected by means of automatic oscillographs from 11 operating power systems, having a total of about 2,800 circuit miles of transmission line at voltages ranging from

26 to 220 kv. The periods of observation were from $1\frac{1}{4}$ to $5\frac{1}{2}$ years. For one-line-to-ground faults, the most frequently occurring apparent fault-resistance, irrespective of fault location, was found to be about 20 ohms (5 ohms for faults at stations), with no great difference as between lines supported on steel structures and on wood structures. However, the studies did not include any lines designed for maximum utilization of the impulse strength of wood.

Since the installation in 1931 of two Petersen coils on a 140-kv system,[7] about 30 other Petersen coils have been installed in this country. With a given arrangement of coils, the residual current in a given exposure, and consequently the induced voltage, is practically independent of fault location. With a directly-grounded or an isolated power system, the induced voltage depends upon the relative locations of fault and exposure, and may vary over a wide percentage range. In grounded-neutral systems, residual currents large enough to make limitation desirable for inductive co-ordination purposes usually occur only where the neutral is grounded either directly or through a low impedance, and large reductions are obtainable through the employment of a Petersen coil.

Line outages preventable by Petersen coils are mainly those due to lightning flashovers. To clear faults not extinguished by the coil, recourse is usually had to short-circuiting the coil, either directly or through an impedance, and relaying out the faulty section of line. Unless a fairly high impedance is used, the residual current would usually be quite large under this condition. But the proportion of all faults that can be cleared without by-passing the coil (reported as from 70 to 90 per cent in various cases[8]) is sufficient to be of real value, even when no impedance is used in series with the by-pass breaker.

From the standpoint of inductive co-ordination, other types of neutral impedance, such as resistors, can be used for current limitation, and their status does not appear to have changed in the past ten years or so. Fault-current limitation has certain advantages from the power operating standpoint, for example, in limiting voltage dips, possible loss of load, and shock to system during faults,[7] and for improving transient stability.[9] Against these advantages, certain disadvantages have to be weighed, if the neutral impedance is to be high enough to have a large effect in most low-frequency induction cases. These questions center mainly upon dynamic overvoltage and the closely related matter of system insulation, and upon relaying.[10]

Dynamic overvoltages vary over a power system because of the flow of residual current through line impedances. In figure 2 a few results are shown from a recording oscillograph study of dynamic overvoltages on overhead systems under operating conditions.[11,12] The percentage of observed cases in which the voltage exceeded twice normal was about 64 for the isolated system, about 5 for the system grounded through Petersen coils, and about 34 for the resistance-grounded system (75 ohms). These records from operating systems were in general accord with the results of staged tests.[13] No evidence was found of the building-up of high sound-phase voltages, such as have been inferred to be possible from theoretical studies of the "arcing-ground" phenomenon. The view has recently been expressed by other investigators that such a voltage build-up is not to be expected if the arc path is between fixed contacts in open air, as in the case of an arc to ground on an overhead line, but that it may occur if the arc occurs in a confined space[14] or between breaker contacts whose separation is increasing.[14,15]

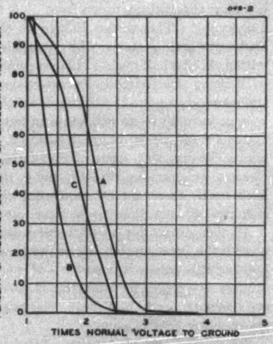

Figure 2. Dynamic overvoltages—magnetic-oscillograph observations on operating systems

A—800-mile 140-kv isolated system
B—274-mile 140-kv Petersen-coil system
C—158-mile 26-kv 75-ohm resistance-grounded system

Questions concerning system insulation[16,17,18] may arise when it is proposed to apply a relatively high neutral impedance to a system previously operated with neutral grounded directly. The nature of these questions can be indicated briefly by recalling that a lightning arrester must operate at an impulse voltage amply below the insulation level of the protected apparatus and still not operate or pass current on dynamic voltages likely to be impressed upon it by power sources in the system. While there are many factors to be considered in suiting lightning-arrester protection levels to the insulation levels of equipment, a considerable improvement during the past decade in lightning arresters, together with more detailed knowledge of their characteristics, has somewhat simplified this matter.[19]

Relaying questions involved in neutral impedance applications to systems previously operated with direct ground connections[10] include the possibility of changes in ground relays or the adoption of ground relaying if not previously used, additional potential transformers (when ground relaying is not already in use), possible changes in bushing current transformers, and in some cases, a change to a different relaying system in some portions of a network (to maintain proper selectivity). Ground relaying frequently presents difficulties for systems grounded at more than one point through high impedance.

Frequency of Occurrence and Duration of Ground Faults

The frequency with which induced voltages of various magnitudes may occur in an exposed communication system depends, first, upon the frequency of occurrence of ground faults in the power system and, second, upon their distribution with respect to the locations of exposure and power sources. In most cases, appraisals of these factors are largely matters of judgment. Valuable guidance is usually obtainable from operating experience on the power system or similar systems in the same locality, and from consideration of the character of line construction, connected line mileage, and number and location of neutral grounds. Duration of ground faults can usually be approximated well enough from relay and circuit breaker characteristics.

A simple illustration of the bearing of the relative locations of exposure and power source upon the frequency of occurrence of induced voltage is given in figure 3. In diagram (*A*) the exposure is at an unfavorable location—practically every ground fault would result in residual current through the exposure. On the other hand, an exposure located as in diagram (*B*) would be appreciably affected only by the faults between stations *B* and *C*. In diagram (*A*), it would be advantageous, if practicable, to transfer the neutral ground to station (*B*). Moreover, this would not increase the number of cases of induced voltage in the exposure of diagram *B*, but would probably increase the voltages themselves.

In studies already referred to,[5,6] a large amount of data was collected regarding the characteristics of ground faults. As to frequency of occurrence there was considerable variation among systems (from 5 to 60 faults per 100 line-miles per year, averaged over the periods of observation), and also from year to year on a single system. Lightning was assigned as the known or probable cause of from 50 to over 90 per cent of the faults, depending on the system. On the average, some 10 per cent of the faults were cleared in about 10 cycles, and about 10 per cent required two seconds or more for clearance. The percentage of faults involving each of two phase wires and ground, but at different points, was small—from about one-half per cent to about six per cent in three systems for which data were available. This point is of interest in the use of neutral impedance for inductive co-ordination, since, if an exposure lies between the two fault points on different phase wires, a high induced voltage may result, the neutral impedance being ineffective for limiting ground current in this situation.

In the past ten years, the importance of direct strokes in the problem of protecting transmission lines from lightning has become fully recognized. This has led to a series of investigations which have greatly increased our knowledge of lightning,[20,21,22] and to the development of several methods of preventing interruptions to service from lightning. Measures for preventing ground faults or power follow-up after spark-over, or for limiting the duration of dynamic current to ground faults are directly helpful in low-frequency inductive co-ordination. In the remainder of this section brief comments are made on the developments that seem most significant from this point of view.

The use of ground wires on steel-tower lines results in a substantial reduction in ground faults from lightning.[23] The combined use of counterpoises and ground wires has given further improvement where tower-footing resistance or earth resistivity is high.[23,24] Where the counterpoise is continuous, it, as well as the ground wires, makes a further contribution by reducing coupling coefficients.

Possible improvements in line operation through the use of the insulating properties of wood,[25,26] while perhaps somewhat less attractive than they appeared some ten years ago, have also resulted in reduction of frequency of occurrence of faults. Quite recently renewed interest in the subject has led to a comprehensive experimental study of fundamental factors.[27]

The protector tube (expulsion protective gap), for controlling lightning flashovers on power lines, first used commercially in 1931–32, is finding increasing application, and has been used on lines covering the voltage range from 13.8 to 138 kv.[28,29] This device interrupts the flashover and restores the insulation within about a half cycle. It has no effect in limiting short-circuit current magnitude, and thus none in holding down the voltage induced in an exposed communication circuit. But its great rapidity of action limits the energy transferred. Because it operates directly upon the fault itself, there are no sequential circuit-breaker operations to be considered.

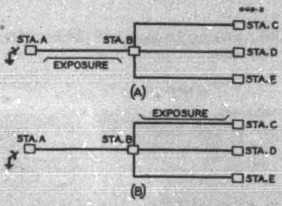

Figure 3. Relative locations of exposure and grounded sources of power—illustrative diagrams

Another device for arc-extinction purposes is the Petersen coil. From the viewpoint of this paper, it is perhaps of more interest as a means for limitation of residual current, and has been discussed above under that heading.

Relay and circuit-breaker developments have been toward substantially higher speeds of operation, both for new installations and in the modernization of existing installations. These developments have made available breakers with an operating time of about 0.13 second, and quite recently still higher speed (about 0.085 second). These figures do not include relaying time. The exceptional speed of about 0.05 second over-all has been reached in the breakers for the Boulder Dam lines.[30,31] Like "lightning-proof" line construction and the use of expulsion gaps, high-speed breakers have, of course, no effect upon short-circuit current magnitudes. But they have the advantage of not being limited to the clearance of lightning flashovers. As used in combination with high-speed reclosing immediately following high-speed opening of circuit breakers, there will probably be some cases where fault recurrence after reclosure will diminish the inductive co-ordination benefit resulting from the high-speed opening.

From the low-frequency induction standpoint, the most notable improvements in relaying have been increases in speed of response, the further development and use of pilot-channel methods,[32,33,34] and particularly the combination of the two to replace earlier methods of selection, with much greater rapidity of relay action. In some recent applications, the time to energize the breaker trip circuit has been reduced to about one cycle (60 cycles per second) by using high-speed relays in combination with pilot channels,[35] with practically simultaneous relay operation at the two ends of the line section.

These developments in the power art, tending to reduce both the frequency of occurrence and the duration of ground faults, are all favorable to low-frequency inductive co-ordination. From a practical standpoint, the resulting degree of benefit depends upon the extent of use of these developments, and upon which are more widely used, since they are not all equally favorable. These matters, of course, are not static and the actual extent of the resulting reaction upon low-frequency inductive co-ordination is not easy to specify in quantitative terms.

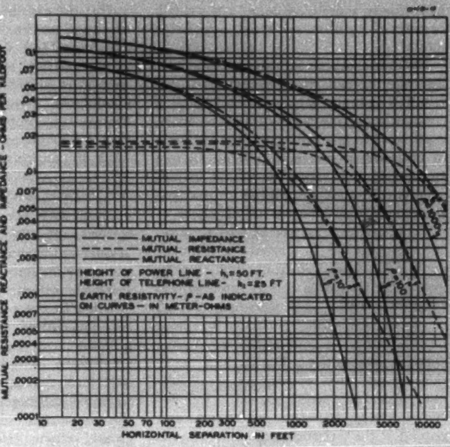
Coupling and Shielding

COUPLING

The residual power current, when multiplied by the coefficient of coupling between the power and telephone circuits, gives the open-circuit longitudinal induced voltage in the telephone circuit. In determining this coefficient of coupling, or mutual impedance, the telephone and power circuits are treated as ground-return circuits, regardless of normal conditions of operation as metallic circuits. Coupling coefficients can be determined as precisely as required. Methods of calculation have been considerably advanced, and in preliminary estimates, calculated values are generally used. As a rule, however, expenditures for co-ordination measures should only be made on the basis of test data or experience.

In earlier work, the calculation of coupling coefficients was based on the "equivalent ground plane" theory. This theory was first superseded by one in which account is taken of the finite conductivity of the earth, assumed to be homogeneous. Another assumption, retained from the earlier theory, is that the primary or "disturbing" circuit is straight and of infinite length. Experimental work interpreted by this theory showed that the earth is frequently far from homogeneous and that its resistivity varies widely from place to place, from 5 to over 10,000 meter-ohms in extreme cases, with corresponding variations in coupling coefficients between circuits. This variation is much smaller at close than at wide separations. For example, at a separation of 50 feet, the 60-cycle mutual impedances between parallel circuits are about 0.36 and 0.63 ohm per mile for resistivities of 10 and 1,000 meter-ohms, respectively. At 5,000 feet separation for the same resistivities the figures are about 0.0035 and about 0.1. These relationships are shown in more detail in figure 4, which is taken from a comprehensive report[36] on coupling between ground-return circuits.

Figure 4. Variation of mutual impedance with separation



This theory has since been expanded to allow certain departures from homogeneous earth structure,[37,38,39] including a horizontally stratified earth of two layers with different resistivities. In many situations calculated values based on this assumption have agreed well with experimental results.

While the assumption of an infinitely long, straight primary circuit is satisfactory in most practical cases, there are situations in which its application is accompanied by uncertainty. Examples are where the grounding points of the power and telephone lines are in proximity at one or both ends of the exposure, and where breaks in direction occur in one or both of the circuits. Investigation of these "end-effect" phenomena have led to the development of formulas[38,39,40] in which no restrictions are placed upon the lengths of the circuits or the routes they follow, nor upon the relative locations of their end (grounding) points.

In application to practical cases, these "finite-line" formulas require a great deal more labor than the infinite-line theory. Theoretical and experimental study of the need of better precision than the latter affords has not been completed, but work done to date indicates that results based on this simpler theory need scrutiny, particularly if the earth resistivity is high, in cases of proximity of grounding points, and of breaks of direction in either circuit, toward or away from the other, and not compensated by breaks at other points in the opposite direction. If reasonably accurate knowledge of earth resistivity is available, the effect of proximity of grounding points can be approximated by an easily calculated correction.

In "probe-wire" tests for determining earth resistivity, a number of secondaries (probe wires), parallel to a primary line and at various separations, are used. If, for some of the wires, the separations are too large compared to the length of the primary, errors in the earth resistivity, as inferred from the infinite-line formula, can be avoided by applying relatively simple corrections based upon the finite-line theory.

Earth resistivity depends on the earth structure at the location in question. A compilation of data has been made of earth resistivities in various parts of the country, including correlation of geological formation with resistivity,[41] which will serve as a general guide in preliminary estimates.

SHIELDING

In this discussion, the word "shielding" is used in a restricted sense to mean a reduction in an induced voltage, this reduction being caused by the action of currents brought into existence by the same primary source that causes the induced voltage. The conductors in which these currents exist are called shielding conductors or shields. They may be associated with the primary system (for example, power line ground wires) or with the secondary system, (for example, telephone cable sheaths) or they may be especially placed purely for shielding purposes. Grounded metallic structures such as water or gas pipes also frequently provide shielding. The effect of extensive networks of such pipes, as in cities, is essentially the same as a lowering of the earth resistivity, and is accounted for directly in the coupling coefficients rather than as shielding.

Results of experimental and theoretical work done on shielding by the Joint D. & R. Subcommittee up to about five years ago have been published in an engineering report.[42] Here methods and data are given for calculating shielding from conductors on open-wire telephone or power lines, from the sheaths of aerial or underground power cables, and from the sheaths of aerial or underground telephone cables with or without tape armor. An approximate method for estimating shielding from grounded-core conductors in telephone cables is included.

The information in this report shows, for example, that the shielding from a three-eighth-inch steel ground wire on a 60-cycle transmission line is 10 per cent or less; two high-conductivity aluminum-conductor steel-reinforced ground wires afford a shielding of about 55 per cent. At 60 cycles, shielding by the lead sheath of a full-size telephone cable is of the order of 50 per cent if the sheath is in good contact with the earth. When the sheath is wrapped with tape armor (two 40-mil steel tapes on the larger-size cables), this figure is increased to 80 or 90 per cent. Shielding due to power cables depends upon the construction and may vary anywhere from 40 to 70 per cent. The effects of buried pipes are usually difficult to estimate unless the pipes are welded, because of the unknown resistance of pipe joints.

Existing methods for calculating shielding take account where necessary of distributed admittance between shielding conductors and ground. More recently, consideration has been given to the effects of currents in the disturbed conductors themselves. In long telephone cables, such currents are established in part because of the distributed admittances of the core conductors, and in part they result from the use, in normal operation, of equipment connected from conductors to ground at terminals and at intermediate repeater points. The shielding effects* of these currents, particularly those through terminal equipment, are of substantial importance. For example, considering a 50-mile repeater section of full-size cable inductively exposed, the 60-cycle voltage between conductors and ground at the terminals, where the sheath is grounded, may be only some 5 to 15 per cent of the open-circuit longitudinal voltage, that is, the induced voltage with the effects of all shielding currents, both in the sheath and in the core, eliminated. At points away from terminals, considerably larger voltages may exist between conductors and sheath and more particularly between conductors and ground, when as a result of two-directional power current feeds, shielding effects may be partially cancelled. In construction and maintenance work, a part or all of the core conductors may be open, eliminating or reducing shielding currents in them. In this case, voltages across breaks in conductors are important, as well as voltages to sheath or ground.

The usual methods for calculating reductions of longitudinal induced voltage by shielding assume in effect that in any measurements made, for example to verify the calculations, the potential of a distant ground is taken as reference. However, in cases of very close association between shielding and shielded conductors, of which cables are the best example, the voltage between these conductors (core and sheath, in a cable) is frequently of as much interest as the voltage between some point on the core and a distant point.

Questions of the character of those just discussed are on the current program of the Joint D. & R. Subcommittee. Another matter which is receiving attention is shielding by communication conductors grounded through the operation of protectors. This involves rather difficult calculations, with results liable to considerable error.

TESTING METHODS

Even with the advances already described in the theory of coupling between ground-return circuits, tests are generally necessary for important situations. Considerable attention has therefore been devoted to the possibilities of simplified test procedures. When lines are available for test, coupling can usually be determined most satisfactorily by a direct measurement of induction at the fundamental frequency, or by measuring the induction into short temporary ground-return circuits (probe wires). For situations in which such measurements cannot easily be made, development work on a d-c method of determining earth resistivity, using simple, readily portable apparatus has had promising preliminary results. It is expected that a report covering this and other methods will be available before long.

The development of vacuum-tube voltmeters of high sensitivity has been of value in connection with coupling measurements where one circuit is energized with a small current and the voltage induced in paralleling exploring wires is to be measured.

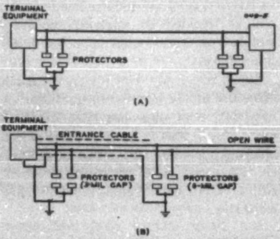


Figure 5. Diagrams to illustrate application of telephone open-space protectors

Susceptiveness

As pointed out in the Conwell-Warren paper,[1] the effects of low-frequency induction upon a communication circuit depend upon the magnitude and duration of the induction. They include service interruption due to protector operation, damage to plant, the possibility of acoustic or electric[43,44] shock, false signaling, and telegraph-signal distortion. Some of these effects, such as interference with signaling, may occur at induced voltages below the protector breakdown value. However, the more serious effects from low-frequency induction are usually associated with induced voltages sufficient to operate protectors.

An interruption to service results from permanent grounding of protectors, which occurs if the discharge current through the protector is not promptly extinguished, or if this current is very high. Protectors are employed as required for the protection of persons, equipment, or property, as at central offices, stations, etc. A simple diagram to illustrate the application is given in figure 5*A*. Where the circuit is in open wire and entrance cable is involved, an additional set of protectors is placed at the junction of the open wire and the entrance cable, as shown in figure 5*B*, to protect the cable. The protectors designed for location near terminal equipment usually consist of carbon blocks with a separation of three mils between blocks. Protectors used at the end of the cable are similar carbon blocks with about six-mil spacing. Use is also made occasionally for special purposes of a similar protector with ten-mil spacing.

The behavior of a protector of this type, particularly where the spacing is as close as three mils, depends upon a number of factors. Purely for illustrative purposes, figure 6 has been prepared from laboratory test data taken at 60 cycles. It shows the breakdown voltage distribution for a sample run of new three-mil blocks under certain specific conditions as to duration of test voltage and impedance of the test circuit. These factors, and also the number of operations to which the blocks have previously been subjected, affect the breakdown voltage characteristic as well as the ability of the protector blocks to withstand discharges without becoming short-circuited.

When induced voltages sufficiently high to break down the protectors are impressed upon the gaps on the two sides of the line to ground, there is a certain amount of dissymmetry in the resulting arc voltages across these two gaps. This sets up current through the receiver which may cause acoustic shock to the person using the receiver.

Voltages which might affect telephone linemen in the course of their work are voltages from wire to nearby grounded objects, and voltages between one wire subject to induction and another wire grounded at nearby or distant points.

---

* From a different point of view, these effects are merely the voltage drop in the disturbed conductors, resulting, of course, from the currents set up in them by the disturbing field. This voltage drop is a self-impedance drop and the shielding is "self-shielding". When, as in the earlier discussion, the current producing the shielding is in a conductor (for example, the cable sheath) which is not itself one of the disturbed conductors, the shielding is also a voltage drop, but it is due to the *mutual* impedance between the shielding conductor and the disturbed conductors.

The reactions upon the subject of this paper of progress in the electrical communication art in the past decade are

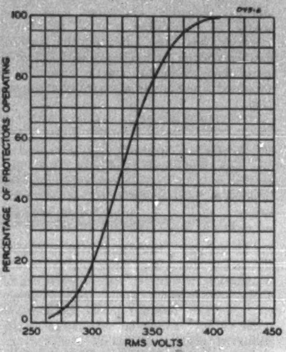

Figure 6. Breakdown characteristics of telephone open-space protectors—laboratory tests at 60 cycles

less direct than those of advances in the power industry, reviewed above. On the other hand, in the development of specific remedial devices for low-frequency induction situations, much has been done with regard to measures for use in communication systems. The effects of trends in the communication art and developments in communication system remedial measures will be discussed in succession.

New Telephone Carrier Systems

The principal developments in wire telephone and telegraph transmission during the past few years have been toward increased use of carrier circuits.

With the availability of a system which permits the use of wider frequency bands and correspondingly more carrier channels on open-wire lines,[45] some open-wire routes can be economically developed for larger numbers of circuits instead of being replaced by cable.

In existing toll cables, the application of carrier transmission makes increases possible in the number of channels per sheath,[46] which is bringing about a tendency toward smaller physical dimensions for new toll cables. This in turn means that the shielding against low-frequency longitudinal induction would tend to be diminished unless counteracted by deliberate increases in the sheath dimensions. Shielding effects exerted on each other by cables in close proximity, which depend essentially on the total conductance of all the sheaths, would be reduced by a reduction in either the size or the number of cables.

While these developments in carrier telephony, of which the coaxial cable[47] is the most recent, present new features, principally in connection with shielding, they do not change the nature of the technical problem in an essential way. An increase in the number of communication channels per physical pair of wires, and in the number of channels along a given route, of course emphasizes the desirability of protecting the system from disturbance. However, low-frequency induction, in this respect, does not stand on a different footing from other possible sources of disturbance, aside from limitations which may be encountered in the application of specific remedial measures, such as relay protectors, to the telephone line.

Signaling

Increasing use is being made of recently developed d-c signaling systems, composited or simplexed in a manner similar to superposed telegraph, for through supervision and dialing on both local and toll trunks. These systems are provided with terminal equipment for neutralizing longitudinally induced voltage or ground potential, the functioning of which requires that it be connected to a conductor exposed to the voltage to be neutralized. For this purpose, one wire of the pair, or in the case of a phantom group, one wire of the group, is used. This normally leaves one wire for each trunk for dialing or supervision. While this arrangement reduces the susceptiveness of the system, there have been some cases in which the neutralization was apparently insufficient to take care of low-frequency induction under normal operating power-circuit conditions. This matter is under investigation.

Induction from power-system voltages under normal operating conditions sufficient to disturb grounded party-line ringers has also been experienced in some cases of exposure to rural power circuits consisting of a single phase-wire and multigrounded neutral. A ringing system has been developed, and is in some use, employing cold-cathode gas-discharge tubes to keep the circuit free of ringing grounds except when the tubes are operated, as by ringing voltage. In its present form, however, this arrangement would frequently be ineffective against induction from rural-line exposures, of the type just mentioned, since the tube operating voltages must be held within magnitudes adapted to satisfactory operation of ringing systems.

Considerable work has recently been done and is continuing on the general question of the susceptiveness of telephone equipment, particularly equipment for signaling and supervisory purposes, to low-frequency induction.

Telephone Protectors

Development work is in progress in connection with the protectors used at stations and at junctions of open-wire and cable, particularly study of the possibilities of material having a nonlinear resistance-voltage characteristic. While some of these materials appear to be valuable for special purposes, the studies have not thus far resulted in any device that seems likely to replace the present protector for general application. As has been noted in a recent paper,[48] a 3,000-volt carbon electrode gap has been developed for use as a specific measure in cases of joint use at the higher voltages.

Relay Protectors

Relay protectors installed at terminals or at the junctions of open-wire lines and cables greatly reduce the probability of permanent protector grounding, and also minimize acoustic disturbance in the communication circuits. In addition, relay protectors installed along the line minimize the possibility of electric shock to linemen by reducing potential to ground throughout the entire line. The operation of relay protectors of course results in an interruption to the communication circuits for the duration of the disturbance.

The multigrounding type of relay protector operates so as to ground all wires of a telephone line at the point where the apparatus is installed when the voltage to ground at that point rises sufficiently to operate any one of the open-space protectors associated with the installation. The discharge of current through any one or more of the open-space protectors operates a master relay, which operates the relays associated with each protector. These individual relays each short-circuit the associated protector gap and prevent permanent grounding. The improvements over the earlier equipment[49] have been (*a*) substitution of an a-c master relay, in series with a saturating transformer, for the earlier combination of rectifier and d-c relay; (*b*) speeding up of operation, which is now completed in about 0.025 second; (*c*) increase in current-carrying capacity of the short-circuiting relay contacts; (*d*) increase in minimum release current (master relay); (*e*) increase in capacity of master relay to absorb heat without damage. For relatively rare situations, in which the master relay may be held up by normal induction after the power-line fault causing its operation has cleared, means may be provided for opening all the short-circuiting relay contacts after a suitable interval, these contacts reclosing quickly if the fault condition should prove not to have cleared.

In addition to this "multigrounding" type of relay protector, a "unit type", applicable to a single pair of wires only, has been developed. It is used principally at points where protectors of the ordinary type would be subject to frequent grounding and where, because the location is remote, maintenance would be delayed or expensive.

Neutralizing Transformers

Neutralizing transformers installed along a communication line provide counter electromotive forces against induced longitudinal voltages, and permit the line to operate normally through inductive disturbances. A type of transformer for neutralization on voice-frequency toll circuits has been developed and has proved satisfactory in a service trial, where 12 were used in series in two inductive exposures totaling about 50 miles in length. Each transformer is wound with 24 secondary wires. The primary, consisting of two telephone wires, is grounded at each end of the exposure and between each two consecutive transformers. This trial installation proved satisfactory both in connection with neutralizing induced voltages and in meeting the circuit transmission requirements under normal operation. Additional installations have not been made as other means have offered more economical over-all solutions of specific cases. Further development work would be required to produce a transformer adequate for circuits over which carrier frequencies are transmitted.

A unit-type neutralizing transformer, to take care of a single circuit, has also been developed. This device consists of a single primary winding with two secondary wires. Where more than a single circuit is involved, a number of units can be used with the primaries in parallel. An important application of this device is in connection with maintaining uninterrupted communication service to power stations or substations, at times of power disturbances which cause large rises in the potentials of station grounds with respect to distant points.[50] Two sizes are in use, one for 4,000 and one for 2,000 volts (60 cycles). Frequently use can be made of a cable sheath for the primary or part of it. These transformers are now in operation in a number of places.

Acoustic Disturbances

The copper-oxide rectifying element[51] has superseded the earlier combination of step-up transformer and protector gap as a means of reducing acoustic disturbances to telephone operators. Tests and operating experience have shown that the copper-oxide element is about as effective as a reducer, and has no net effective transmission loss. It is smaller and lighter than the earlier type and the indications are that it will have a satisfactory service life in use at central offices.

In circuits with telephone repeaters, the nonlinear characteristics of the vacuum tubes cause the tubes to function as devices for limiting acoustic disturbances. A study of the quantitative relationships has been made, including determination of the factors to be taken into account in order to realize as fully as practicable the power-limiting possibilities.[52]

Conclusion

The foregoing review will have shown, it is believed, that the net result of development of the past ten years has been favorable to low-frequency inductive co-ordination. Over-all improvement has in fact occurred, and has accompanied a growth in the power and telephone industries which, though less than expected ten years ago, has not been inconsiderable. It is estimated that in the decade increases in the neighborhood of 30 per cent have taken place in power generating capacity and in mileage of transmission circuit in the range from 22 to 66 kv. In the Bell System, telephone toll circuit mileage has increased some 22 per cent and telephone stations about 7 per cent.

In an important degree, the contribution of the Joint D. & R. Subcommittee to this favorable result has been due to the assistance it has received from operating power and telephone companies. This helpful relationship will, it is hoped, continue in the working out of the problems that remain and the new ones to be expected from future growth and development.

Summary

We recapitulate here principal developments of the past decade in the problem of low-frequency induction, with remarks on the resulting present status and future plans for study of different phases of the problem.

General

1. Studies of effects in actual low-frequency inductive exposures have been useful in developing general procedural methods, but have indicated the need of further work on certain items, with reference particularly to facilitating the appraisal of proposed situations in advance of construction.

Influence

2. In the calculation of residual currents, the more important gaps have been filled by the experimental determinations of the impedance of ground-faults on operating systems, and of the impedances and admittances of lines (especially cables).

3. In residual-current limitation, probably the most interesting development is the installation, within the last three years, of about 30 Petersen coils. The Petersen coil generally limits residual currents to small values. Little or no change in the status of other methods of fault-current limitation has taken place. As heretofore, the application of fault-current limitation is primarily a matter of its reaction on power-system operation, although developments have somewhat simplified this question.

4. Frequency of occurrence of ground faults has been reduced by improvements in the insulation of power lines, including improved ground-wire application and features of structural design. In the reduction of duration of ground faults, the protector tube is probably the most important development from the standpoint of low-frequency induction. Others are increased speed of circuit-breaker operation, including high-speed relaying and closely simultaneous clearances at both ends of the faulted line section, and (except for permanent faults) the Petersen coil.

These developments have had a definitely favorable reaction on low-frequency inductive co-ordination, although it is impracticable to ascertain the extent of this, taking the country as a whole.

Coupling and Shielding

5. The theory of the mutual impedances of ground-return circuits has been extended to cover circuits of arbitrary lengths and contours, and now includes also certain types of heterogeneous earth structure. Some further work is desirable in simplifying the engineering application of the theory to types of problems which may be encountered.

6. Coupling tests should be made before final decision in important cases. Development work has cheapened and simplified field testing methods and apparatus, and is continuing.

7. Methods and data for calculating reductions in longitudinally induced voltages resulting from shielding currents in usual types of shielding structures have been published. In the case of telephone cables, the voltage between conductors and sheath

(as contrasted with longitudinally induced voltage) is of interest, and in long cables, shielding by currents in the conductors as well as by those in the sheath is important. These matters are currently receiving attention.

8. Shielding by currents in conductors which become grounded through protector operation is difficult to estimate, although it has frequently been found to be of considerable importance. Additional investigations of this factor are to be carried out.

Susceptiveness

9. Possibilities of using toll cables of relatively small physical dimensions, and of new structural designs, presented by developments in the application of carrier to cables, require consideration of changes in the inherent shielding afforded by the cable structure. These and allied questions may continue to require study for some time.

10. The use of composited d-c toll-line dialing and through-supervision systems is increasing. Inclusion in these systems of arrangements for neutralizing induced voltages reduces their susceptiveness to low-frequency induction, although further study of inductive co-ordination with these and other signaling systems is needed.

11. Development work on the relay protector has been substantially completed. This device has had a good record in use as a specific measure of co-ordination.

12. Two types of neutralizing transformers have been developed. One, for neutralizing ground potentials on communication lines serving power stations, is being successfully used in practice. The other, designed for toll-line use, proved satisfactory in field trial, but the probable field of use is small.

13. A copper-oxide device for reducing acoustic disturbances has been developed for use at operators' positions. Experience indicates that it is generally satisfactory.

Discussion

L. F. Roehmann (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): The authors gave an excellent review of the progress in the art of low-frequency inductive co-ordination which has been realized in this country during the past decade. It might be appropriate to add that during that interval substantial work has been done on the other side of the Atlantic also.

In 1926 and 1930, the CCIF issued "Guiding Principles Concerning the Means for Protecting Telephone Lines Against the Adverse Effects of High-Current or High-Voltage Lines." Last year, an entirely new edition has been published ("Guiding Principles Concerning the Protection of Telecommunication Lines Against the Adverse Effects of Industrial Power Lines"). This publication, containing 150-odd pages, is an up-to-date textbook on inductive coordination rather than just a set of recommendations. It climaxes the co-operative efforts of the International Mixed Commission for the Study of Inductive Interference, the CCIF, and a number of other international groups and organizations. Power and communication engineers of France, England, Germany, Switzerland, Sweden, and many other countries contributed to its setting-up.

The publication is written in French but an English translation has been prepared. While many of the minor details are different in the two hemispheres, the basic conceptions are of course the same.

J. W. Milnor (The Western Union Telegraph Company, New York, N. Y.): This paper discloses a very healthy condition in the development of low-frequency inductive co-ordination. A comparison with that presented in 1931 by Messrs. Conwell and Warren makes it evident that the past ten years have produced few actual changes in the basic method of attack; instead there has been a continuous advance in the knowledge of the problem, of the mathematics which represents the variable conditions, and of the apparatus and equipment necessary to provide the desired safety and stability of service.

The scope of the discussion is so broad that within the necessary space limitations the authors have been able to describe only the most prominent advances. Fortunately there is included a bibliography which in itself is an index of the extent of the progress, and which should be of much value to the reader who desires more intimate knowledge of any phase of the problem.

The authors have dealt chiefly with the transient low-frequency interference which occurs particularly at times of fault conditions in the power system. They have perhaps underemphasized the continuous interference which may occur during normal power operation, and which often has serious effects especially to high-speed telegraph circuits, although it is rarely damaging to the telephone.

J. O'R. Coleman: Mr. Trueblood and I greatly appreciate L. J. Roehmann's remarks regarding the report of the Comite Consultatif International Telephonique. The English edition of the report of the 11th Plenary Meeting held in Copenhagen, was published in 1938 by the International Standard Electric Corporation, and contains considerable interesting information. Due to the many different conditions existing in European practice, technical, economic, and social, we do not feel that in general the work of the CCIF can be directly applied to American practice, although many of the technical findings are useful.

A Precision Rotating Standard for the Measurement of Kilowatt-Hours

J. H. GOSS
ASSOCIATE AIEE

A. HANSEN, JR.
ASSOCIATE AIEE

THE accuracy with which electrical energy is metered is dependent upon the apparent measured value of the kilowatt-hour used. Quite independent of the electrical operating characteristics of the watt-hour meters used or the accuracy limits within which they are adjusted, the average accuracy of a group of watt-hour meters is directly affected by the difference between the value of the kilowatt-hour used and the true value.

The apparatus used to derive the unit while satisfactory for reference does not lend itself to practical use in the checking and calibrating of watt-hour meters in commercial installations. Specially designed and compensated induction-type watt-hour meters, which are calibrated in the laboratory approximately as outlined in table I, have long been used as commercial working standards. These watt-hour meters are known as portable standard watt-hour meters and have been developed to a high degree. In fact, so well do they perform that an improvement in the method of standardizing them is justified.

It is the purpose of this paper to describe an improved system for maintaining the value of the kilowatt-hour to be used primarily for the calibrating and checking of portable standard watt-hour meters.

Analysis of Errors in Method of Checking Rotating Standards

Table I shows the limits of probable error present in the various steps of a particular system. It is evident that all of the values given in table I could add up to be (+) or could add up to be (−) if a sufficiently large number of checks were taken. The probability of either of these two conditions occurring is much less than is the probability of some steps compensating others due to differences in the sign of the errors. Should all errors add (+) the result would be a +0.245 per cent variation, and if all (−), a −0.245 per cent error. It is important, therefore, to obtain some idea of the most likely way the error of the various steps will combine to determine what over-all accuracy is to be expected.

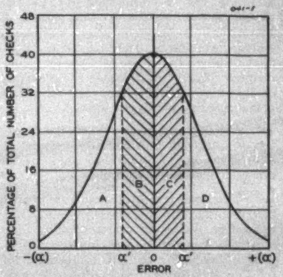

Figure 1. Absolute error in per cent

Paper 40-41, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 13, 1939; made available for preprinting January 3, 1940; released for final publication March 5, 1940.

J. H. Goss is engineer in charge, works laboratory, and A. Hansen, Jr., is engineer, General Electric Company, Lynn, Mass.

Consider a theoretical distribution curve, figure 1, and for the purpose of illustration let the abscissa represent a system of errors similar to table I. To avoid confusion the error limits have been designated $\pm\alpha$. If a large number of checks are made, figure 1 will represent a plot of the results. The tests showing zero error will be the most frequent, but the extreme errors will occur in a small percentage of the readings when the component errors have the same sign.

The technician must realize that with a small number of readings the average value may not be a fair one. If it should occur that in five readings a high (+) error is obtained with four smaller (+) errors, the average would be (+) and would depart appreciably from the absolute value. It is important that a sufficiently large number of readings be taken to show up the individual readings with large variations from the mean.

As the total area under the curve, figure 1, represents all of the readings, half of the area will represent half the total number of readings. The areas A, B, C, and D have been divided to make each equal to one-fourth the total area $(B+C=A+D)$.

The abscissa of B is $-\alpha'$ and of C is $+\alpha'$. The combined areas $B+C$ represent half the total number of readings, and it is, therefore, reasonable to state that one-half of the readings taken are probably within the area $B+C$ and are therefore, within $\pm\alpha'$. This value of the abscissa $(\pm\alpha')$ will be referred to as the probable error.

Precision Rotating Standards Method

The schematic diagram shown in figure 2 gives the circuit and essential elements of a system of three precision rotating standards. This system is capable of maintaining a high degree of accuracy. It will first be described in its component parts and then its method of operation, together with actual performance data, will be given.

A. ROTATING STANDARDS

The rotating standards shown in figure 3 are used as the measuring elements. These were made by taking a commercial portable standard watt-hour meter, removing the register, and rewinding the current coils for a five-ampere current rating only.

The standards were removed from their cases and mounted as shown in figure 4 in a walnut case. Incandescent-lamp housings and lens systems were mounted above the meters and photoelectric cells in suitable housings were mounted below the case. Glass windows were provided in the top and bottom of the case to allow the light from the light sources to be focused through a small hole in the meter disk onto the photoelectric cell below. The case was completely sealed against dust and mounted on a vibration-free concrete wall in a (22 degrees centigrade) controlled-temperature room. Each rotating standard was carefully compensated for both unity and 0.5 power-factor lagging temperature errors (class I and class II errors).[2]

Each rotating standard, together with its light source and photoelectric cell, is considered as a unit having no functional relation with the other two. For the purpose of identification these will be called precision rotating standards numbers 1, 2, and 3.

B. TRANSFORMERS

The standards were designed for 120 volts and five amperes, but a high-

F—Voltage regulator

accuracy current transformer having a Mumetal core is used to allow the standards to operate at five amperes under all test conditions. The ratios available are shown under *B* in figure 2 and allow for all points required for the commercial checking of portable rotating standards. The current transformer has a ratio error within 0.04 per cent on all coils and a phase angle error within one minute on all coils.

A potential transformer is provided for 240-volt operation.

Not only are the transformers designed for low inherent errors, but they are considered as an integral part of the precision rotating standard circuits and all calibrations made in accordance with table I are made on the combination. This method of calibration was employed using instruments for all current ratings to check the meter and transformer combination. Although the ratio and phase-angle errors were determined for the transformers, they were not used in arriving at the calibration of the standards.

C. Photoelectric-Cell Testing Relay Circuit and Auxiliary Switching

A photoelectric-cell amplifier, figure 2, is provided which operates a counter circuit which can be preset to energize through the potential relay the potential circuit of one or more portable standard watt-hour meters and to keep the potential circuit or circuits energized for the preset number of revolutions of the precision rotating standard.

By means of a suitable switch, precision rotating standard number 1, number 2, or number 3 may be used to control the portable standard watt-hour meters under test. The repeatability of the relays and photoelectric circuit is in the order of ±0.01 per cent for ten revolutions. The precision rotating standard being used runs at the selected load continuously and only the standard under test is started and stopped.

Method of Use and Results

Each of the three precision rotating standards is operated continuously when not being used for test work at two per cent of rated current and with rated potential applied. This eliminates any error due to potential-coil heating.

The error in the calibration of each of the precision rotating standards is determined by repeated checks in accordance with the steps shown in table I. At no time since the beginning has any change been made in the adjustments of any of the three standards. It is then desirable to cross-check the precision rotating standards in terms of one another using a portable standard watt-hour meter as the transfer medium. If the standard used for the transfer has a known history of calibration, it is valuable as a reference to show up any major changes in absolute values of any of the precision rotating standards.

It would be desirable not to introduce the fourth standard for the purpose of intercomparison. It is possible to use one of the three precision rotating standards for this purpose, and this will eventually be done. The results of using a transfer have been quite satisfactory to date.

Figure 5 shows the results of such an intercomparison over a period of five months for the five-ampere 120-volt load point operating at unity power factor. Precision rotating standard number 1 is assumed to be correct and number 2 and number 3 are plotted in terms of their deviation from number 1.

The maximum variation in number 2 from the original reading is +0.06 per cent and of number 3, −0.06 per cent over the five months' period. Note that at the end of the period number 2 is +0.03 per cent above the original reading and number 3 is −0.01 per cent below its original reading.

Figure 6 shows the same intercomparison as figure 5 except that the load point used was 120 volts, five amperes, and power factor 0.5 lagging. It is to be expected that a greater variation will be obtained using this load due to other variables operating. For example, variation in phase angle, wave form, frequency, and temperature are more effective in

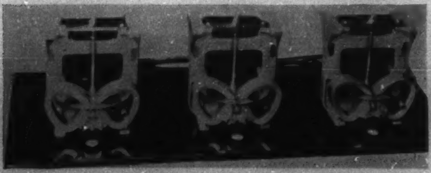

Figure 3. Precision rotating standards without case

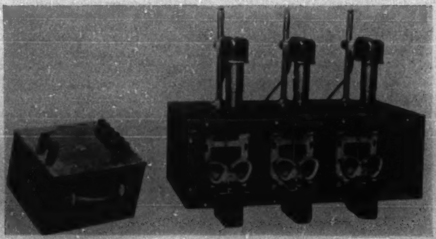

Figure 4. Precision rotating standards complete with light sources, photoelectric tubes, and precision current transformer adjacent

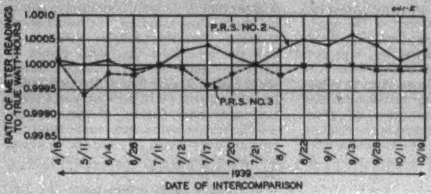

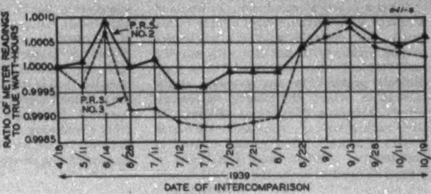

Figure 5. Intercomparison data on precision rotating standards corrected in terms of standard number 1

Five amperes, 120 volts, 60 cycles, unity power factor

producing calibration change than at unity power factor. The maximum variation of precision rotating standard number 2 is +0.09 per cent and of precision rotating standard number 3, −0.12 per cent. At the end of the period, number 2 is +0.06 per cent above the original reading and number 3 is +0.02 per cent above the original reading. No change in the adjustments were made at any time after the initial readings were taken.

Figure 7 shows the results of 36 separate checks made over the five months' period in accordance with table I. The most probable error in absolute calibration is ±0.04 per cent from the mean. The initial instrument check was assumed to be correct for the purpose of plotting the data in figure 7. It is evident that the initial point was low by −0.06 per cent and a better value of the absolute calibration is the peak ordinate or +0.06 per cent above the initial reading. The distribution curve was drawn by first determining the mean and standard deviation for the results of the 36 checks and calculating the ideal curve to fit the data.

Certainly, these standards are running together within far closer limits than any single instrument check can be relied upon to reveal. This is, however, the ideal condition for obtaining the true mean value in accordance with table I. If the precision rotating standards remain constant and the interchecks reveal that they are, then their calibration will approach the value of the maximum ordinate in figure 7. As all these standards were intercompared, figure 7 represents the instrument check on each of the standards.

Should some factor influence all of the standards to drift at exactly the same rate, the intercheck would not reveal the drift. As continual periodic instrument checks are obtained, curves similar to figure 7 can be plotted and compared one with another to show up this drift.

The actual use of this method for checking portable standard watt-hour meters is evident. Each precision rotating standard has a definitely established calibration so that one revolution of the disk under a given load corresponds to a definite kilowatt-hour value. By placing the portable standard watt-hour meters to be checked as shown in figure 2, any one of the three precision rotating standards may be selected to deliver a given number of kilowatt-hours to them. The ratio of the reading of the individual portable standard to the known value of the precision rotating standard is a measure of its accuracy.

The average of the calibration obtained using each of the three precision standards in turn to control the portable standard watt-hour meter or meters under test will give the highest precision. In practice, however, the additional accuracy is not justified because of the additional time required.

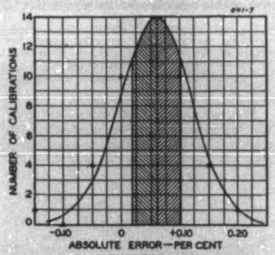

Figure 7. Curve of distribution of absolute error for repeated checks of precision rotating standards

Five amperes, 120 volts, 60 cycles, unity power factor

The high accuracy of the photoelectric testing system makes it necessary to take runs of no longer than 60 seconds for any given point. This greatly speeds up the calibration check of the portable standard watt-hour meters.

Figure 6. Intercomparison data on precision rotating standards corrected in terms of standard number 1

Five amperes, 120 volts, 60 cycles, 0.5 power factor lagging

Conclusions

1. It has been demonstrated that for the highest accuracy of calibration of portable standard watt-hour meters using instruments, a number of readings must be taken and properly weighted.

2. A new system of precision rotating standards has been described that has high inherent accuracy together with fast operation.

3. With care it is entirely practical by the system described to insure the absolute accuracy of the kilowatt-hour used in checking standards to within 0.06 per cent at unity power factor loads and 0.12 per cent at 0.5-power-factor lagging loads.

Discussion

George B. Schleicher (Philadelphia Electric Company, Philadelphia, Pa.): The authors are to be congratulated upon their contribution to the important field of maintaining the accuracy of laboratory-standard watt-hour meters. The elimination of "start-and-stop" errors in the so-called master standard, by causing it to rotate continuously during the calibration, serves also to eliminate such errors from the working standards when their corrections are determined by tests *over the same intervals that are used in service.*

From a practical standpoint the limits of accuracy as covered in table I appear rather small. For example, holding a wattmeter setting within 4/100 per cent with varying load (table I, step *C*-1) would be a very difficult problem in the average utility laboratory where the source of energy supply is from a distribution system. In the calibration of standard watt-hour meters with wattmeters, manual control to maintain a constant load introduces a human element of error, and there is a need for an *automatic* means of obtaining *constant wattage* independent of voltage variation. We have succeeded in accomplishing this, at least experimentally, by electronic means.

In the standard described by the authors, bearing friction is reduced by operating the standard only at full-load speeds, but possibly further improvements can be made in this direction. While the magnetic suspension is not new, modern magnetic materials, as for example Alnico, have made possible the design and construction of practical meter bearings of this type. This construction may prove highly desirable for service meters. Figure 1 of this discussion shows such a bearing developed by Walter C. Wagner of the Philadelphia Electric Company, and constructed of magnet materials contributed at our request by the General Electric Company. In the figure the air gap indicated by the arrow shows a greatly enlarged view of the bearing. Meter-performance tests over extended periods show consistent results superior to those of pivot and jewel bearing construction particularly at light load, thus permitting accurate performance to be maintained in standards and meters at lower operating speeds than with the conventional types of bearings. This type of suspension would undoubtedly further improve the uniformity of performance of the precision standards described by the authors.

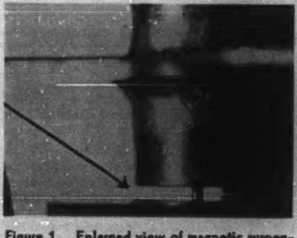

Figure 1. Enlarged view of magnetic suspension on watt-hour meter

The arrow points to the air gap which represents the bearing surfaces

W. J. Seeley (Duke University, Durham, N. C.): I should like to ask a question which is old but the philosophy of which is quite intriguing. It may have been answered to the satisfaction of manufacturers long ago, but not enough information has been given in print to put at rest a question which comes up with fair regularity. It is conceivable that by proper construction and adjustment the greater part of the weight of the rotor on the lower jewel may be removed by magnetic attraction, thus considerably reducing the friction loss. The question then is this: In an effort to reduce the rotation losses of your precision rotating standard, had you considered the possibility of reducing the weight of the rotor on the jewel by the use of a permanent magnet suspended just above the upper end of the shaft?

Wm. M. Young (Ohio University, Athens): Of particular interest in this paper is table I giving assigned values to the various sources of error encountered in standardizing and calibrating rotating standard watt-hour meters. It is assumed that all measurements were made using sinusoidal waves of current and voltage and that the authors were not concerned with irregular wave forms.

The question naturally arises as to whether or not the errors in the instrument check are inherent and whether they cannot be minimized by any standardizing laboratory if the equipment is properly aged and maintained at a constant temperature and if repeated trials are made and the results plotted on a probability curve. Naturally any laboratory can, in this way, reduce the 0.11 per cent accumulated error in the wattmeter's calibration by using proper care.

Might I ask the authors about the 0.03 per cent error assigned in *C*-3 "change in wattmeter from check value". Are there any data available on the accuracy of the determination of this error? Naturally it can be partially reduced if the time interval between checking the meter and using the meter for a watt-hour meter calibration is reduced to a minimum.

It would seem that the greatest contribution of this paper lies in the substitution of

1. A machine-switching machine for a hand-switching machine. This naturally affects the magnitude of errors *C*-4, *C*-5, and *C*-6. They total, as indicated by the table, 0.065 per cent.
2. Multiple standards cross-checked against each other in place of human observation for *C*-1.

In figure 5 might I ask about the drift of the readings in rotating standards with time? It would seem that an aging effect might be here showing up and that the meters would eventually tend to stabilize at some constant error.

In figure 7 might I ask why the point at 0.05 per cent error was not used in the determination of the probability curve? It would seem that more data should be taken before a good probability curve can be drawn and that results should not rely on merely 36 readings.

A. E. Vivell (Princeton University, Princeton, N. J.): It is gratifying to see that the actual title of this paper describes the meter as a "precision" meter and not as a "primary" standard as announced in the advance notices. It would be unfortunate to handicap such an excellent and interesting development with a misnomer.

The calibration procedure described is most thorough and provides a very comforting check on the constancy of these meters. However, the figures in table I seem to show a probable error of about 0.08 per cent in the watt-hour used in checking the rotating standard. It would seem, therefore, that the probable variation of 0.04 per cent from the mean shown in figure 7 is somewhat low. An exceedingly slight change in only four of the calibration points (at 0 and +0.10 per cent) could make the curve much flatter. If the point at +0.05 per cent were taken into account the probable error would be increased to about 0.08 per cent and the theory of probability restored to favor.

This paper again brings home the fact that the measurement of a watt-hour is handicapped by the lack of a simple scheme of measurement. When the meter error becomes less than the error of the standard it is time to work for better standards. It would be interesting to know if the authors have considered trying to improve their watt-hour by means of some other scheme of calibration; for example, a calorimeter or some other energy device.

A. Hansen, Jr.: An analysis of the discussions of our paper reveals four general points of comment: first, the limits of errors shown in table I; second, the manner in which our data were handled and the derivation of the probability curve shown in figure 7; third, bearing considerations; and fourth, the apparent better accuracy of the watt-hour meter than the calibrating standards.

The values shown in table I represent the results obtainable with extremely careful control of each step starting with the standard voltaic cell. Special sources of power of as constant regulation as possible are used without the use of electronic regulators. The authors feel that the values shown are representative for the method, and are the result of a number of years of experience.

An automatic device for holding load might be applied to some advantage in the system described. Up to the present time, however, the authors have had no experience with such a device.

The authors recognize the fact that insufficient data were obtained to fix positively error magnitudes. It was the purpose of the paper to describe a method and a system of arriving at a precise value of the watt-hour.

The probability curve in figure 7 was plotted considering all calibration values and is not sketched in from the grouped data plotted but was calculated from the actual data.

Inasmuch as the precision rotating standards rotate continuously at full-load speed for all check points, the variations due to bearing friction are practically negligible. A magnetic-suspension type bearing is an interesting device in view of the new magnetic materials available.

At the present time no practical way of obtaining the value of the watt-hour is known to the authors that is basically different from the method outlined in table I. Energy-equivalent methods have been experimented with such as the calorimeter. The difficulty in using the calorimeter is not with measuring the heat values, but in determining the correction for heat loss.

In conclusion, the authors wish to express their appreciation for the very excellent criticisms they have received and hope that all questions have been satisfactorily answered.

Lightning Currents in Arresters at Stations

I. W. GROSS
MEMBER AIEE

W. A. McMORRIS
MEMBER AIEE

A CO-OPERATIVE field investigation of the lightning currents discharged by arresters at stations was undertaken in 1936, by the engineering departments of the American Gas and Electric Service Corporation and the General Electric Company. Data have previously been published on the currents discharged by distribution lightning arresters[1,2,3] but little information is available on the duty required of arresters located in stations, where considerable influence on incoming lightning waves may be produced by a large number of circuits connected to one bus, by the capacitance to grounded steel work in the station, by the more or less sheltered location of some stations, and by types of construction commonly used for transmission lines.

The data so far obtained show that there are large variations in the number of arrester discharges from season to season, and that due to local conditions the duty on arresters is far more severe in some locations than others, making it difficult to arrive at a representative average. Hence the investigation is to be continued in order that the effects of these factors may be better determined. Some redistribution of field installations may be made to provide more information on points where the data have been meager.

Scope and Conduct of Investigation

In this investigation the field work was carried on for four years (1936–1939) on four American Gas and Electric Company properties; the Ohio Power Company in Ohio, the Appalachian Electric Power Company in Virginia, the Atlantic City Electric Company in New Jersey, and the Indiana and Michigan Electric Company in Indiana. This diversified territory provided an opportunity for studying lightning conditions as affecting arresters, on properties employing different practices, and with isokeraunic levels varying from 27 to 45 thunderstorm days per year.

Figure 1. Wooden bracket supporting two surge-crest-ammeter links on lead to lightning arrester

Measurements of arrester discharge currents were made with surge-crest-ammeter links[4] mounted on each leg of each three-pole arrester, in a straight part of the conductor between the arrester and the line. Typical field installations are shown in figures 1, 2, and 3. Links were serviced approximately every two weeks during the lightning season for four years, and any which indicated that current had passed through the arrester were removed for calibration and replaced with demagnetized links. The magnetized links were checked in the field in some cases, but received a final calibration at the Pittsfield works of the General Electric Company.

The current measuring installations are listed in table I, where they are grouped

Figure 2. Surge-crest-ammeter link installations on all three poles of 33-kv oxide-film lightning arrester

Paper 40-59, recommended by the AIEE committee on protective devices, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 24, 1939; made available for preprinting January 3, 1940; released for final publication February 28, 1940.

I. W. Gross is research engineer, American Gas and Electric Service Corporation, New York, N. Y.; W. A. McMorris is in the lightning-arrester engineering department of the General Electric Company, Pittsfield, Mass.

A large number of people in several organizations have contributed to make an investigation of this type possible and to correlate the data in suitable form for presentation. The authors wish to express their appreciation to the Ohio Power Company, the Appalachian Electric Power Company, the Atlantic City Electric Company, and the Indiana and Michigan Electric Company, where the field work was done; and to those in the Engineering Departments of the General Electric Company and the American Gas and Electric Service Corporation who supervised the work and analyzed the records. Acknowledgment is made to the helpful assistance of George D. Lippert of the American Gas and Electric Service Corporation for correlating the records on which the paper is based, and to Doctor K. B. McEachron and D. D. MacCarthy of the General Electric Company for their assistance in organizing and directing the progress of the investigation.

1. For all numbered references, see list at end of paper.

according to several different classifications. The installations were confined to arresters in stations only, and included arresters connected to lines where they entered the stations, arresters on or immediately adjacent to power transformers, and arresters connected to station busses. The arresters were of several different designs. Approximately 75 per cent were designated by the manufacturer as "station type" and 25 per cent as "line type". All circuits involved operated with grounded neutrals, at line-to-line voltage ratings of 11 to 132 kv.

One hundred three-pole arresters were equipped in 1936 for the measurement of lightning discharge currents. This number was increased each year until 1939, when 166 were under investigation. The total three-pole arrester-years for the four-year period was 580*, making an average of 145 under study each year. On the basis of single-pole arresters, the study included 1,734 arrester-years, or an average of 433.5 each year.

Number of Records Obtained

A total of 459 records of lightning currents discharged by single-pole arresters were obtained during the four-year period, or 0.79 records per three-pole arrester per year. The maximum number of single-pole records obtained during the four-year period on any one three-pole arrester was 29, and three other arresters yielded 24 records each.

Table II summarizes the number of records per arrester for the 85 three-pole arresters that remained in service during the entire four-year period. These were all on Ohio Power Company and Appalachian Electric Power Company circuits, where the severity was above the average for the four operating companies.

Table II. Number of Records Per Arrester During Four-Year Period, 1936–39

Magnitude of Currents

The highest individual arrester discharge current recorded was 15,000 amperes, and 16 measurements or 3.5 per cent of the total were 5,000 amperes or more. Arresters at certain locations were subjected repeatedly to high discharge currents.

In many cases there were several arresters in one station connected so that they could operate in parallel. The current which any one might have been called upon to discharge, in the absence of the others, may be estimated by adding together the currents recorded simultaneously in all of the arresters. The highest value obtained in this way for any one phase is 19,000 amperes.

The current measurements obtained are summarized in table III, where the maximum, minimum, and the median current (the current exceeded in 50 per cent of the cases) are listed for several operating conditions, together with the number of current measurements and arrester installation-years upon which the values are based. Figure 4 shows how the 459 current records were distributed with regard to magnitude.

Table III. Summary of Recorded Arrester Discharge Currents, 1936 to 1939 Inclusive

Polarity of Currents

The polarity of 401 records, or 87.6 per cent of the total, was negative, and of 58, or 12.4 per cent, was positive. This proportion is intermediate between the previously reported values of 63 per cent negative for distribution arrester discharge currents,[1] and 95 per cent negative for lightning currents measured in steel tower legs of transmission lines.[5] In this investigation, the data do not show any recognizable effect of line construction, locality, or circuit voltage rating on the proportional numbers of negative and positive polarity records. Figure 5 shows that the distribution of the negative-polarity records with regard to current magnitude was substantially the same as for positive-polarity records.

Variability Between Localities and Seasons

The data shown in figure 6 indicate that the number of arrester discharges varies considerably from season to season, and is consistently greater in some localities than in others. Seasons which are severe in some localities are comparatively mild in others. The greatest number of discharges per arrester per year was 3.84 for the Appalachian Electric Power Company in 1936, and the smallest number was 0.22 for the Indiana and Michigan Electric Company in 1938. The ratio between these two extremes is 17.5 to 1. During the entire period of the investigation, the average number for the former company was over 8 times that for the latter, although the average isoke-

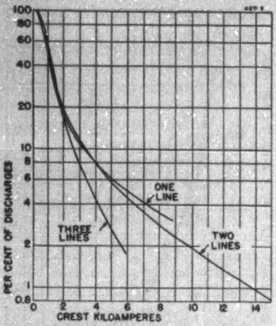

Figure 8. Effect of number of connected lines on magnitude of currents discharged by arresters

Curves show per cent of discharges with current magnitude at least as great as indicated, and include data only from stations with one arrester each

raunic level for the former location was less than twice that for the latter. Among the several factors which may have contributed to this difference are the flashover values of the lines involved, height of conductors above ground, presence of ground wires, and the frequency with which installations were inspected for magnetized links. However, when all known variables are taken into account, it is evident that the number and magnitude of discharge currents is strongly influenced by local conditions which can be evaluated only by experience over a period of several years. Therefore, it must be recognized that conditions may be encountered in service which are quite different from those reported here.

Effect of Circuit Voltage

The data were examined to determine the effect of variation in the rated operating voltage on the severity of arrester discharge currents, but any consistent trend which may exist was obscured by other influences such as the effects of line construction and local conditions. It may be possible to evaluate this effect when more data are available.

Effect of Line Construction

Figure 7 and table III show that arresters connected to wood-pole lines without ground wires are subjected to considerably more severe duty than are arresters on other types of circuits, particularly with regard to the number of high currents which they must discharge. They must pass currents of 5,000 amperes or more about ten times as often as other arresters. Less difference exists between the other types of construction included in figure 7.

Table IV. Multiphase Arrester Operations

Type of Line Construction	Number of Cases Involving: One Phase Only	Two Phases	Three Phases
Steel towers, with ground wire	55	21	18
Steel towers, no ground wire	13	2	3
Wood poles, with ground wire	38	11	4
Wood poles, no ground wire	30	26	28
Mixed line construction	11	6	7
Total	147	66	60
	Per Cent of Cases Involving: One Phase Only	**Two Phases**	**Three Phases**
Wood poles, no ground wires	35.7	31.0	33.3
Other three types of construction	64.2	20.6	15.2

Effect of Multiple Circuits

In figure 8 are shown the results obtained at stations operating with only one lightning arrester each. The curves, shown for cases where one, two, or three transmission lines enter the station, indicate that there is some reduction in the magnitude of currents which the arrester must discharge, as the number of lines is increased. Five per cent of the recorded arrester currents exceeded 6,000 amperes where there was one line, 5,600 amperes where there were two lines, and 3,700 amperes where there were three lines.

It is significant that of the 85 three-pole arresters included in table II, including many at stations with several arresters, over 50 per cent were at stations with four or more incoming lines; yet all of the 11 arresters which produced ten or more records each were at stations with three lines or less.

Multiphase Operations

Data from all arresters involved in the investigation are summarized in table IV to show how many times records of discharge current were found on only one phase of a three-pole arrester, on two phases simultaneously, and on all three phases simultaneously. This table indicates that for wood-pole lines without ground wires, more than one phase was involved in about two-thirds of the cases, and for other types of construction, more than one phase was involved in only about one-third of the cases. For each type of construction the number of two-phase operations was approximately equal to the number of three-phase operations.

Discharge of Arresters Connected in Parallel

In some of the stations there was an arrester connected to each line where it entered the station, and additional arresters connected to the station bus or power transformers or both. The total number of three-pole arresters in any one station, so connected that they could operate directly in parallel, varied from one to ten. Data are presented in table V showing the number of times records of discharge currents were found simultaneously on several such arresters in one station, indicating that they probably discharged in parallel.

The maximum number of arresters apparently discharging in parallel, was five, in a case where there were but five arresters in the station. Three arresters

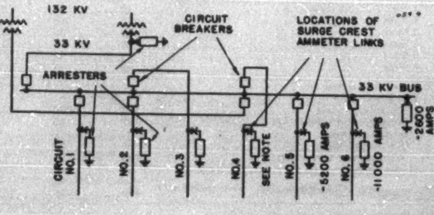

Figure 9. One-line diagram of 33-kv connections at Newcomerstown substation, Ohio Power Company

Current of −450 amperes recorded on phase 2 of this arrester. All other records on phase 1 discharged in parallel on three different occasions, with 4, 8, and 10 arresters respectively in the station, so connected that parallel operation was possible. Two arresters discharged in parallel on 24 different occasions, involving the same two arresters in 10 cases.

A case at a 33-kv substation is of particular interest. The circuit arrangement was as shown in figure 9. Circuits number 2 and number 5 in this sketch were on wood poles and the remaining circuits were on steel towers. All had overhead ground wires. A current of 11,000 amperes was discharged by one pole of the arrester on circuit number 6. Simultaneously a discharge of 5,200 amperes was recorded through the same phase of the arrester on circuit number 5, and one of 2,600 amperes was recorded through the same phase of the bus arrester. No discharges were recorded on the other phases of these arresters, and the only record obtained on the arresters on the other lines which were two, three, four, and five bays distant from the arrester which carried the heaviest current, was 450 amperes on another phase of the arrester connected to circuit number 4.

The curves of figure 10 show that the individual arrester currents discharged when two or more arresters discharge in parallel are in general higher than when only one of the parallel arresters discharges.

Equipment Failures

The only failure of lightning arresters included in the four-year investigation, involved one old-type arrester operating under compromise conditions on a 132-kv circuit, with the possibility of voltage being applied in excess of the manufacturer's rating. This application was made in an attempt to protect power transformers which were of an old design, with an impulse strength considerably below present-day standards. It therefore appears that the arresters involved in the investigation have a discharge capacity adequate for discharges of the magnitude and duration which they experienced.

Five cases of bushing failure occurred. The bushings concerned were of an old type, some ten or more years old, and due to the fact that all cases were internal bushing failures, it is believed they are chargeable to deterioration rather than lack of adequate protection. In one case the current through the arrester was 12,000 amperes; in another case, 2,400 amperes; and in three cases, no currents were indicated. It is interesting to note that in all five cases, the bushings which failed were of the order of 30 to 70 circuit feet from the nearest lightning arrester. Four of the bushings were rated and operating at 33 kv and one at 22 kv.

One bus-support flashover occurred on a 33-kv bus. This was of an old design, the electrical characteristics of which are unknown.

Protection Given by Arresters

The amount of benefit obtained from the arresters becomes apparent when calculations are made to show how many of the recorded disturbances would have resulted in voltages considered unsafe in the absence of arresters. In table VI, the values assumed for maximum safe impulse voltage are 80 per cent of the proposed AIEE and ASA standard chopped-wave impulse test voltages for new transformers. The corresponding arrester discharge current is calculated on a traveling wave basis, assuming one incoming and one outgoing transmission line, with an arrester at the station. All discharges recorded on lines of the rating in question, with currents above the calculated value, are then considered to have resulted from traveling waves which would have produced unsafe voltages in the absence of arresters. A mathematical analysis on this basis is not valid for the higher-current discharges resulting from direct strokes near the stations, in which case successive reflections of traveling waves must be taken into account. Such waves would, however, almost surely be unsafe, and since the current magnitudes would likely be much higher than the values shown in table VI, the mathematical analysis would indicate them to be unsafe.

The table shows that a considerable number of the recorded surges in the 132-kv class, and nearly all of the recorded surges in lower-voltage classes would have been unsafe in the absence of arresters. The number of unsafe waves per three-pole arrester per year decreases progressively as system voltage is increased, ranging from 0.72 for 11–33 kv to 0.31 for 132 kv.

Note that the calculated values in table VI are based on the assumption that a traveling wave entered the station on one conductor only, and that there was a second three-phase line connected to the station bus to provide a path for an outgoing traveling wave. These assumptions were made to simplify the calculations, and appear to represent a fair approximation of the average conditions. For 7.4 per cent of the recorded discharges, dead-end circuits were involved, which would increase the severity as compared to that for the assumed conditions. For 75 per cent of the discharges, lightning currents entered the station over two or more conductors, which would also increase the severity. For 40 per cent of the discharges, there were more than two lines connected to the bus, which would reduce the severity.

Conclusions

1. The data obtained indicate that the number and magnitude of discharge currents through arresters in stations is strongly influenced by local conditions and seasonal variations, and representative values can be determined only by experience over a period of several years. Therefore, conditions may be encountered in service which are quite different from those reported here.

2. A total of 459 single-pole arrester discharge currents were recorded in a four-year investigation, on an average number of 145 three-pole arresters located in stations. This is a rate of 0.79 single-pole discharges per three-pole arrester per year, which may be compared to the previously published rate of 0.51 discharges per single-pole arrester per year on rural distribution circuits, which have exposure somewhat comparable to transmission systems.

3. Additional discharges below the limit of current sensitivity of the recording apparatus probably occurred. Also in case of two or more discharges through any single-pole arrester between successive inspections, only one current record would be obtained; hence discharges undoubtedly occurred without being recorded for this reason.

4. One three-pole arrester yielded a total of 29 single-pole records during the four-year period, and three others yielded 24 each.

5. The highest discharge current recorded through one pole of an arrester was 15,000 amperes. There is no reason for believing that this is the highest discharge current that can occur, and it is expected that as more data are accumulated, substantially higher currents will be recorded.

6. Arresters at certain locations were subjected repeatedly to high discharge currents.

7. Approximately 3.5 per cent of the arrester discharge currents were of 5,000 amperes or more.

8. The polarity of 87.6 per cent of the records was negative, and of 12.4 per cent was positive. The proportion of positive currents was lower than previously obtained for distribution arrester discharge currents and higher than for lightning currents in steel tower legs of transmission lines.

9. The difference in number of records obtained in different localities during the four-year period was as great as eight to one. An attempt to evaluate the factors that might have contributed to this difference, such as the number of thunderstorm days per year, types of line construction, line operating voltage, and the interval between inspections to locate magnetized links, did not account for this great a difference in severities. It is evident that the severity is influenced by the severity of the storms, including seasonal variations, and other local factors that can be determined only by experience, and cannot be accurately predicted on the basis of data obtained in other localities.

10. Any consistent trend which may have existed in the severity of discharge currents, as influenced by the circuit voltage rating, was obscured by the effects of other variables. It may be possible to evaluate this effect when more data are available.

11. Arresters connected to wood-pole lines without ground wires were subjected to more high-current discharges than other arresters. Discharges of 5,000 amperes or more occurred about ten times as often as with other types of line construction.

12. For arresters connected to wood-pole lines without ground wires, more than one pole of the arrester was involved in about two-thirds of the cases when discharges were recorded. For arresters connected to other types of lines, more than one pole of the arrester was involved in only about one-third of the cases.

13. The data indicate that increasing the number of lines connected to a station bus decreases the magnitude of the current which any one lightning arrester in the station is required to discharge.

14. In stations where there were several arresters so connected that they could discharge directly in parallel, the records obtained indicate that five arresters discharged in parallel on one occasion, three arresters in parallel on three different occasions, and two arresters in parallel on 24 different occasions. The individual arrester discharge currents were in general higher when two or more arresters discharged in parallel, than when only one of two or more arresters in a station discharged.

15. The data indicate that when a lightning current enters a station on a line equipped with a lightning arrester at the station entrance, the lightning voltages reaching other parts of the station are not usually sufficient to cause the operation of other arresters.

16. Damage to equipment at stations during this four-year investigation was of minor importance. The only lightning arrester which failed was of an old type, applied under compromise conditions. The five cases of bushing failure involved 22- or 33-kv bushings of obsolete design, the insulation of which appeared to have been in doubtful condition.

17. Calculation of the traveling-wave voltages associated with the recorded arrester discharge currents shows that for 11- to 33-kv lines, about 0.72 records per three-pole arrester per year, or 93 per cent of those recorded, represented lightning voltages that would have been dangerous to station equipment in the absence of arresters. Corresponding values for 44- to 88-kv lines are that 0.41 records per three-pole arrester per year, or 73 per cent of those recorded; and for 132-kv lines that 0.31 records per three-pole arrester per year, or 35 per cent of those recorded, would have been dangerous to station equipment in the absence of arresters. This clearly illustrates the relative number of lightning surges of dangerous magnitude which reach a station not supplied with lightning-arrester protection.

Synopsis: Electric couplings have recently been applied on a large scale in geared Diesel ship drives to couple the engines to the gear. They serve a threefold purpose by acting as a flexible coupling to keep the torsional vibration of the engine out of the gears, as a disconnecting clutch to enable any engine to be cut out of service, and as an aid in maneuvering.

A typical large coupling built for marine service is described, and the general principles and characteristics of this type of device are given. Results of tests taken to confirm the calculated characteristics are included. The operation of the coupling as an aid in maneuvering is described. A summary of applications to date is given with a discussion of possible applications other than ship drive.

ELECTRIC COUPLINGS are devices for transmitting torque by means of electromagnetic forces in which there is no mechanical contact between the driving and driven members. Thus, they differ from electromagnetic clutches which are only friction clutches in which an electromagnet is used to apply the pressure between the friction surfaces. Electric couplings are not new in principle, but their application on a large scale has come only in the last few years. It is the purpose of this paper to review the principles of operation of electric couplings, describe their major application to geared Diesel-engine ship propulsion, and discuss the engineering problems associated with this application.

Probably the idea of an electric coupling is nearly as old as the idea of an a-c generator. There are a number of early United States patents from 1891 to 1906 describing at least the elements of the various types of electric couplings. In 1934 and 1935, the authors made a study of the various types of couplings with the hope of applying them to marine drives. Since 1935, A.S.E.A. in Sweden have equipped a number of ships with electric couplings.[1,2] A 3,000-horsepower coupling was supplied by the Westinghouse Electric and Manufacturing Company to the United States Navy and was quite thoroughly tested. At about the same time, two tankers were equipped with 750-horsepower couplings made by the Elliott Company. Within the past year, the United States Maritime Commission has purchased 116,000 shaft horsepower in electric couplings in 48 units to equip 20 vessels. The extent of electric coupling applications for marine service in this country is given by table I.

Principles of Operation

The electric slip coupling is the type used on all of the large marine applications, and the discussion of the numerous other types will be reserved till the end of the paper. The slip type has poles excited by direct current on one rotating member, and an armature winding, usually of the squirrel-cage type, on the other rotating member. If it is necessary to vary the speed, the winding can be insulated and brought out to slip rings, so that an external resistance can be connected in the circuit to vary the slip.[2] Any relative motion or slip between the two members will induce currents in the armature winding which react with the flux to produce a torque tending to hold the two members close together in speed. This is similar in action to the usual induction motor, except that the rotating field is produced by a direct current in a rotating member instead of by polyphase currents in a stator.

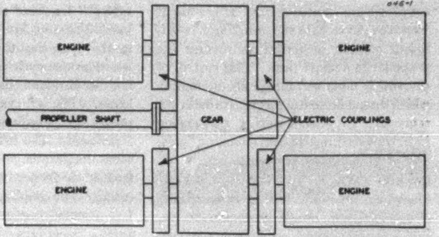

Figure 1. Arrangement of four-engine geared ship-propulsion drive for United States Maritime Commission C-3 cargo vessels, rated 8,500 shaft horsepower

Application to Marine Drives

The principal application of the electric coupling is in geared Diesel-engine ship-propulsion drives as listed in table I. Other applications are described at the end of the paper. The arrangement of a typical marine application is shown in the sketch in figure 1. This is the arrangement being used on the four Maritime Commission *C*-3 cargo vessels listed as number 3 in table I. The four engines drive the single screw through four electric couplings and a two-pinion gear. The manner of mounting the couplings on the engine can be seen in figure 2, and the two members of the coupling are shown in figures 3 and 4.

The coupling performs four functions in the drive, as follows:

1. It acts as a torsionally flexible member between the engine and the gear, eliminating all shocks and limiting the transmission of torsional vibrations produced by the engine to a negligible amount.

2. Since there is no mechanical connection between the two members, the coupling permits a small amount of misalignment. This facilitates the erection of the propulsion plant and increases the reliability in service.

3. It acts as a quick-disconnecting clutch which is not subject to wear, and the torque of which is independent of speed. Any engine can be disconnected in less than a second by interrupting the field current of its coupling. This permits repairs to be made without stopping the ship, and some of the engines can be shut down at low speeds to give greater economy. The greater reliability of multiple-engine drives can be realized only if a disconnecting clutch is available to cut out a faulty engine, enabling the ship to proceed on the good engines. The use of the coupling as a clutch aids in maneuvering as described below.

4. The coupling limits the maximum torque to a safe value. The steady-state pull-out torque is usually about 150 per cent and the transient maximum torque on suddenly applied loads is about 200 per cent. If trouble develops on one engine, such as a seized piston, the electric coupling will limit the torque transmitted to this engine to twice the normal value, and will permit it to stop without injuring the gear and with minimum damage to the engine.

The ease with which electric couplings can be connected and disconnected en-

ables them to be used in maneuvering the ship in a manner which is impossible with other forms of couplings. When a large amount of maneuvering is to be done at low speed, as in going through a close channel or approaching or leaving the dock, the ship can be maneuvered entirely by the use of the couplings. This is done by running half of the engines ahead and the other half astern. The propeller can be connected to either group of engines by energizing the corresponding couplings, and the ship closely controlled by one coupling control lever. This system saves on starting air for the engines, and approaches the Diesel-electric drive in convenience.

The couplings can also be used to reverse the propeller in reversals from full ahead to full astern, as in a "crash stop". In such a reversal, the coupling excitation is removed and the engines reversed. After they are running on fuel at reduced speed in the astern direction, the coupling fields are energized, and the coupling torque reverses the propeller. Figure 5 shows a test slip torque curve on a coupling and a typical propeller torque curve during reversal,[3] assuming that the engines have been brought to 60 per cent speed in the astern direction before the couplings are excited again. It is evident from the curve that the coupling has sufficient margin in torque to reverse the propeller in a short time. This system of reversal is most advantageous on engines which do not have full torque available for reversal. By disconnecting the engine from the inertia of the gear, coupling fields, and propeller, they can be reversed very quickly, even with rather low torque available, because the inertia to be accelerated is low. With the engine on fuel, full torque becomes available to reverse the heavy inertias of the system and overcome the propeller torque. If the engine has sufficient reversing torque, the maneuvering can be done entirely with the engine, with the coupling acting like a solid coupling.

Characteristics

Losses. There are only three losses in electric couplings—windage, slip or armature I^2R loss, and excitation or field I^2R loss. The core loss is usually negligible, as the operating frequency is ordinarily less than one cycle per second. The core loss is included in the measured slip losses. The slip varies with speed and rating, but is ordinarily between one and 2 per cent. The field loss has about the same magnitude, so the efficiency varies from 95 to 98 per cent depending on the rating. The coupling illustrated in figures 1 to 4 tested just under 1.1 per cent slip and 97.75 per cent efficiency.

Figure 2. Electric coupling mounted on 2,225-horsepower, 240-rpm Diesel engine on shop tests

This is the engine and coupling for the drive in figure 1

Torques. The torques required are determined by the operating conditions for the particular drive. The Maritime Commission engineers realized the full possibilities of using the electric coupling for maneuvering. They specified a minimum torque of 75 per cent for any slip up to 140 per cent to give the coupling some margin in torque over that required by the propeller during reversal. They also specified 150 per cent pull-out, or maximum torque as being sufficiently high to cover all conditions of operation. To obtain high torques at high slips, and at the same time maintain low slip at normal load and minimum weight and space, is a real design problem. Earlier couplings employed single-deck squirrel cages, although some of them used deep bars. The torques of these couplings at high slips were far below the values necessary to reverse the propeller at full ship speed. All couplings being built to the Maritime Commission specifications employ some

form of double-deck squirrel-cage armature winding to increase the resistance at high slips.

Temperatures. All recent couplings have had guaranteed temperature rises of 70 degrees centigrade by resistance, above an ambient of 50 degrees centigrade. These are standard for class *B* insulation on electrical installations in ship engine rooms. This rise applies only to the field, as in the squirrel-cage type of armature there is no insulation, and the temperature is limited solely by mechanical considerations. It is customary to require that the coupling meet the guaranteed temperature rise when transmitting full torque down to 70 per cent of normal speed. This speed was chosen as it is the speed obtained with full torque on half of the engines, and was considered the most severe operating condition likely to be encountered. Theoretically, it would be possible to operate with full torque at half speed when running on one engine of a four-engine drive, but it was not considered that this would be an operating condition. With class *B* asbestos and mica insulation, the machine is practically incombustible and offers much less fire hazard than any device using oil.

Torsional Characteristics. In the cases studied so far by the authors, the electrical coupling has effectively limited the transmission of torsional vibration from the engine to the gears to negligible values. It has also had negligible effect on the critical speeds of the engine. In information previously published about electric slip couplings,[2] it has been said that the coupling does not transmit the torque pulsations originating in the engine. Strictly speaking, this statement is not exactly true, because as shown in appendix *A*, the electric coupling under the influence of pulsating torques acts as a weak elastic member, or a torsional spring of low spring constant. In appendix *B*, there is a further discussion of the effects of this spring constant, giving the reasons why it has negligible effect on the natural frequencies of the engine and at the same time effectively limits the vibrations transmitted from the engine.

Structural Features

The coupling illustrated in figures 2, 3, and 4 is typical of large marine couplings made in this country, especially those for Maritime Commission vessels. The two members are overhung on the gear and engine shafts. Most of the couplings have the inner member mounted on the engine shaft, but the coupling will transmit torque in either direction and the field can be put on the engine. The arrangement to be used depends largely on the amount of inertia desired by the engine manufacturer for satisfactory operation of the engine and the most advantageous placing of the critical speeds.

The field has the poles bolted to the inside of the rim of a fabricated-steel spider. The spider has a flange for bolting to the pinion shaft. The field is put on the outer member because such an arrangement gives more room for the winding, better ventilation, and more accessibility for replacing coils. The coils are made of edgewound copper strap with class *B* insulation of the same type almost universally used in large a-c motors and generators, representing the most rugged construction available. Repairs can be made quite easily by unbolting the pole, sliding it out axially, and installing a spare field coil. The collector rings are bronze and the collector assembly is split for ease of removal. The field is ventilated by air which is taken in through holes in the spider plate, passes axially along the windings, and is discharged at the open end.

The inner member consists of a fabricated spider which has a flange for bolting to the engine crankshaft flange. The core is made of one piece circular punchings shrunk on the rim of the spider. The winding is a double-deck squirrel cage with separate short-circuiting end rings for each layer. The outer layer of high-resistance bars is generously proportioned to absorb the heat produced during reversal of the propeller, since at high slips most of the loss is in the outer layer.

The coupling can be removed or assembled without disturbing the crankshaft or pinion shaft. Provision has been made to move the two members together axially a sufficient amount so that they will clear the spigot fits. In this position, they are centered together by a centering fit and can be bolted together. The entire unit can then be lifted out between the two shafts.

A screen guard is usually placed around the coupling for the protection of the engine room personnel. The brush holder parts are mounted on the gear case. The couplings take their excitation from the ship auxiliary power supply. The control consists of a selector switch operated by the coupling control lever at the engine control station, ammeters to indicate the field current, circuit breakers in each coupling circuit for short-circuit protection, and suitable magnetically operated contactors. Discharge resistors are provided and also a resistor to reduce the coupling field for long operating periods at low speed and low torque. The necessary interlocks are provided to prevent energizing a coupling when the corresponding engine is shut down.

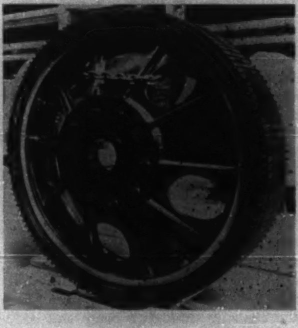

Figure 4. Armature or squirrel-cage member of coupling shown in figure 2

The size and weight of a coupling of given rating increase quite rapidly with the air gap. The minimum gap which can be used is determined by the possible maximum unbalanced magnetic pull. The unbalanced magnetic pull acts in a radial direction and is proportional to the displacement for magnitudes of displacement encountered in normal operation. It acts to increase the displacement, so is equivalent to a negative restoring force. The magnitude of the force depends on the initial displacement which is a function of the bearing clearance, the accuracy of the original alignment, and the possible distortion or misalignment of the ship structure. With conventional ship structure, the misalignment due to the distortion of the ship is very small, as a large deflection of the center of the ship with respect to the ends is produced by a small shear deformation. The air gap used represents a compromise between size and weight on the one hand and magnetic pull on the other. A gap of one-fourth inch appears to be a good compromise for large couplings. Since the magnetic pull may be increased by large bearing clearances, it is desirable to keep these clearances to a minimum consistent with good practice. It should be noted that the magnetic pull in an axial direction is very small.

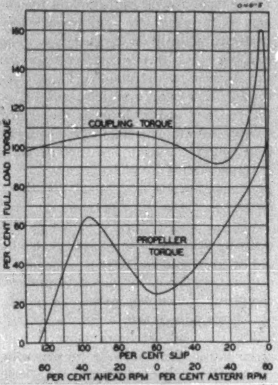

Figure 5. Test slip-torque curve of coupling shown in figures 1 to 4

A typical propeller-torque curve during reversal from full speed is shown assuming that the engine has been brought to 60 per cent speed astern before the couplings are excited

Tests

Since the coupling described above was the first coupling to be delivered to the Maritime Commission, it was given rather extensive tests. The slip-torque curve was measured by locking one member of the coupling through a beam and scale and driving the other member at various speeds with a large d-c motor. The torque measured on the scale was checked by readings of the input to the driving motor. The results are shown in figure 5. The windage was measured by driving the coupling at various speeds and measuring the input. From the curve of friction and windage against speed, the windage could be separated out by the assumption that the friction loss varied directly with the speed while the windage varied as the cube of the speed. The ability of the squirrel cage to undergo a large number of maneuvering operations at reduced speed was demonstrated by locking the inner member, bringing the field member to 70 per cent speed with the excitation off, and then stopping it by applying the excitation. This was repeated 22 times in 9 minutes and 12 seconds with no injurious heating of the bars. Of course, there was no propeller torque to overcome, but the addition of the driving motor gave an inertia comparable to the final installation, and it was felt that the test demonstrated that the coupling had considerable margin above the requirements of actual service.

Further tests were taken on the coupling at the engine-builder's plant. The coupling was mounted on the engine as shown in figure 2, coupling it to a water brake. All of the regular tests on the engine were taken by loading it on the brake through the coupling. This also provided an opportunity for a full-load temperature test on the coupling, demonstrating that it met its guarantees with a good margin. The test setup included a flywheel on the brake side which was roughly equivalent to the mass of the gears and propeller in the final installation. The maneuvering of the ship was simulated, although it was not possible to include propeller torque, and the coupling was able to reverse the mass of its outer member and the flywheel from full speed ahead to full speed astern in from six to eight seconds. The tests indicated that some time in reversal of the propeller would be saved by reversing the engine independently with the coupling disengaged and then using the coupling to stop and reverse the propeller. Several torsiograph records were made to determine the amount of vibration transmitted through the coupling. Typical examples are shown in figure 6. The record marked *A* was taken on the engine crankshaft flange. The vibrations present are the seventh order, or the main firing frequency. They are speed variations rather than shaft vibrations. The record marked *B* was taken on the brake side of the electric coupling. None of the seventh order impulses can be seen on this record. The long swings are due to the natural period of the torsiograph. The high-frequency variations seem to have a frequency of 12 per revolution, and are probably excited by the brake. The amplification on the two records is about the same, record *B* being slightly higher than *A* as shown by the calibration for one degree indicated on the record. The revolution marked off in each record is the same revolution of the engine.

Other Types of Electric Couplings

There are as many possible types of electric couplings as there are types of motors and generators. The more practical types will be discussed briefly.

The slip coupling with squirrel-cage winding has been described in detail. For the purpose of obtaining variable speed, it is possible to insulate the armature winding and bring the leads out through slip rings exactly as in a wound-rotor induction motor. This type will be referred to as a wound-rotor coupling. The problem of controlling the speed through the external resistance is exactly the same as for the wound-rotor motor, except that it is possible to get fine speed adjustments between resistance points by controlling the field current. The efficiency comes down nearly proportional to the slip. This type may find application to Diesel-engine drives where it is desired to run below the lowest operating speed of the engine.

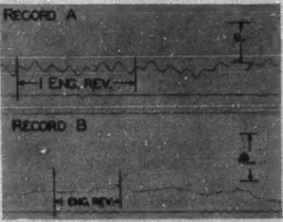

Figure 6. Typical torsiograph records, taken on shop test with engine driving water brake through electric coupling

Record *A* taken on engine crankshaft flange
Record *B* taken on output side of electric coupling

A variable-speed coupling for certain types of load may also be obtained by designing a squirrel-cage slip coupling for high slip and controlling the torque by control of the excitation. This is analogous to controlling the voltage on a squirrel-cage motor. There are two difficulties in this: The high slip necessary for any appreciable range of slip by field control results in lower efficiency at full speed as well as at reduced speed. The other difficulty is the dissipation of the heat from the armature member, since all the slip losses go into this member.

Instead of a conventional squirrel-cage winding, it is obviously possible to use only a solid steel rotor on the armature, making use of the eddy currents induced in its surface. This type gives less pull-out torque and higher slip for the same air gap surface and weight. However, for variable speed by field control, it has the advantage that it can be arranged more readily to dissipate the high slip losses, especially in smaller sizes.

The inductor-alternator principle may be used to make an inductor-type electric coupling. The field is wound peripherally on one member, dividing the air gap into two sections. The flux is unidirectional in each section and is caused to alternate in the armature winding by the relative motion of inductor teeth on the other member. For a given air gap and pull-out torque, more air-gap surface is required in the inductor-type machine since the useful alternating-flux density is limited by saturation to about half of the value in a salient-pole type, due to the superposition of d-c and a-c components of flux. However, where the air gap can be kept very small, this type may result in somewhat cheaper construction for small couplings.

A synchronous coupling can be built by using salient poles and d-c excitation on both members. For most applications this type is less desirable than the slip coupling for several reasons. The increased excitation requirements partially offset the elimination of slip losses, and slip rings are required on both members. The synchronous "spring" torque tends to be higher than in the slip coupling, and if this type of coupling should pull out of step with fields excited, high values of slip-frequency alternating torque would be developed which might excite the torsional natural frequency of the connected mechanical system. Also the presence of field windings on both members makes it difficult to obtain high average torques at high slip.

Other Applications

The application of the slip type of coupling to geared Diesel ship-propulsion drives has been discussed in considerable detail, because that is the largest application of couplings made so far. However, it is interesting to note some of the other possible uses for couplings. This same type of coupling can be applied to any Diesel or gas engine where it is desired to limit the engine torque impulses transmitted to the load. It may also be used for the purpose of limiting the maximum torque and avoiding stalling of the engine. In such applications, the pull-out torque of the coupling must be made less than the stalling torque of the engine. It can be used as a disconnecting clutch to shift gears on an engine which is too large for a friction clutch.

The variable-speed coupling of either the wound-rotor or high-slip squirrel-cage type may be used with a synchronous motor or a constant-speed induction motor to obtain smooth speed or torque control. By use of field control, the speed can be controlled in finer steps than is practicable with a resistance in the secondary of a wound-rotor induction motor. As previously stated, the reduced speed is always accompanied by a reduction in efficiency, but this may not be too serious a handicap for a limited range in speed, for short-time operation at low speed, or for fan or pump drives where the power varies as the cube of the speed.

For a limited range of speed, or for a fan type of load, it is possible in the smaller ratings to obtain speed control entirely with field control of the coupling, using a slip type of coupling with high-resistance squirrel cage, or a solid steel armature.

Conclusions

The electric coupling has filled a definite need in the application of higher-speed Diesel engines to geared ship propulsion. The engineering problems encountered in this application have been satisfactorily solved, as proved by the installations which are now in successful service. As time goes on, a larger proportion of Diesel ship drives are being geared, and the percentage of these geared drives on which electric couplings are applied is increasing rapidly.

Now that the electric coupling has been developed and applied on a commercial scale, it is quite sure to find other applications where its characteristics can be used to advantage.

Appendix A

Electrical Torques Produced by Pulsating Motion in the Electric Slip Coupling

The analogy to the induction motor makes it apparent that the effect of the average torque is to produce a slip between the two members. The effect of any superimposed alternating motion between the two members is to produce both in-phase and quadrature components of alternating torque.

The component of torque in phase with the alternating component of the relative velocity is a damping torque, since it represents energy supplied by the alternating motion. The component of the alternating torque in phase with the angular motion (but opposite in direction) is a transient synchronizing torque, and is equivalent to a weak mechanical spring as far as alternating components of torque are concerned.

The mathematical analysis is based on the following assumptions:

1. That the field resistance is negligible in comparison with the field reactance at the frequencies to be considered.

2. That the squirrel-cage winding can be replaced by an equivalent two-phase winding. This has been proved by applications to induction motors to be quite accurate.

3. That the inductance (L) of these equivalent armature circuits is independent of the relative position with respect to the field. This, in general, is only approximately true, but the effects of variation in inductance will be analyzed further from a physical point of view.

4. The analysis will be carried through for a relative angular motion represented by $\theta=(\omega_s t+\theta_\Delta \sin \omega_\Delta t)$, where θ is the relative angular position of phase a with respect to the field, ω_s is the average angular velocity, θ_Δ is the amplitude of the alternating angular motion, and ω_Δ is 2π times the forced frequency of oscillation. All angles are measured in electrical radians. The actual alternating motion may not be sinusoidal, but it can be resolved into a series of sinusoidal components which can be treated in the same manner.

5. That the amplitude of the angular oscillation θ_Δ, is small, so that $\cos(\theta_\Delta \sin \omega_\Delta t)$ can be taken as unity and $\sin(\theta_\Delta \sin \omega_\Delta t)$ can be taken as $\theta_\Delta \sin \omega_\Delta t$. This is a good approximation up to about 15 electrical degrees. This maximum angle corresponds to about 50 per cent torque transmitted, which is higher than is likely to be encountered. On this basis:

$$\cos\theta=\cos\omega_s t+\frac{\theta_\Delta}{2}\cos(\omega_\Delta+\omega_s)t-\frac{\theta_\Delta}{2}\cos(\omega_\Delta-\omega_s)t$$

$$\sin\theta=\sin\omega_s t+\frac{\theta_\Delta}{2}\sin(\omega_\Delta+\omega_s)t+\frac{\theta_\Delta}{2}\sin(\omega_\Delta-\omega_s)t$$

The equation for voltage and current will be expressed first in volts, amperes, and ohms, and then the torque equation will be expressed in per unit notation in order to give both forms.

$$e_a=-p\left(\frac{M}{L_f}\psi_f\right)\cos\theta=\left(\frac{M}{L_f}\psi_f\right)\left[\omega_s\sin\omega_s t+\frac{\theta_\Delta}{2}(\omega_\Delta+\omega_s)\sin(\omega_\Delta+\omega_s)t-\frac{\theta_\Delta}{2}(\omega_\Delta-\omega_s)\times\sin(\omega_\Delta-\omega_s)t\right]$$

$$e_b=-p\left(\frac{M}{L_f}\psi_f\right)\sin\theta=-\left(\frac{M}{L_f}\psi_f\right)\times\left[\omega_s\cos\omega_s t+\frac{\theta_\Delta}{2}(\omega_\Delta+\omega_s)\cos(\omega_\Delta+\omega_s)t+\frac{\theta_\Delta}{2}(\omega_\Delta-\omega_s)\cos(\omega_\Delta-\omega_s)t\right]$$

The currents can be calculated by using the proper impedance for each frequency. The subscripts s, $\Delta+$, and $\Delta-$ will be used to indicate the impedances determined at frequencies $\frac{\omega_s}{2\pi}$, $\frac{\omega_\Delta+\omega_s}{2\pi}$, and $\frac{\omega_\Delta-\omega_s}{2\pi}$ respectively.

$$i_a=\left(\frac{M}{L_f}\psi_f\right)\left[\frac{\omega_s}{(Z_s)^2}(\gamma_s\sin\omega_s t-X_s\cos\omega_s t)+\frac{\theta_\Delta}{2}\frac{(\omega_\Delta+\omega_s)}{(Z_{\Delta+})^2}\left\{(\gamma_{\Delta+})\sin(\omega_\Delta+\omega_s)t-(X_{\Delta+})\cos(\omega_\Delta+\omega_s)t\right\}-\frac{\theta_\Delta}{2}\frac{(\omega_\Delta-\omega_s)}{(Z_{\Delta-})^2}\times\left\{(\gamma_{\Delta-})\sin(\omega_\Delta-\omega_s)t-(X_{\Delta-})\cos(\omega_\Delta-\omega_s)t\right\}\right]$$

$$i_b = -\left(\frac{M}{L_f}\psi_f\right)\Bigg[\frac{\omega_s}{(Z_s)^2}(\gamma_s \cos \omega_s t +$$

$$X_s \sin \omega_s t) + \frac{\theta_\Delta}{2}\frac{(\omega_\Delta+\omega_s)}{(Z_{\Delta+})^2}\{(\gamma_{\Delta+}) \cos (\omega_\Delta +$$

$$\omega_s)t + (X_{\Delta+}) \sin (\omega_\Delta+\omega_s)t + \frac{\theta_\Delta}{2}\frac{(\omega_\Delta-\omega_s)}{(Z_{\Delta-})^2} \times$$

$$\{(\gamma_{\Delta-}) \cos(\omega_\Delta-\omega_s)t + (X_{\Delta-}) \sin (\omega_\Delta-\omega_s)t\}\Bigg]$$

In per-unit notation, the torque can be determined by the equation developed by R. H. Park[4] and others.

$$T = (i_a\psi_b - i_b\psi_a) \qquad (1)$$

The per-unit currents can be obtained by dividing the actual amperes by rated amperes (I_0). The per-unit flux linkage, ψ_a and ψ_b can be obtained by dividing actual interlinkage by ψ_0 which is the flux linkage corresponding to the resistance drop at full load.

The net flux linkage of each armature circuit can be written:

$$\psi_a = \frac{1}{\psi_0}\left(\frac{M}{L_f}\psi_f \cos \theta + i_a L\right)$$

$$\psi_b = \frac{1}{\psi_0}\left(\frac{M}{L_f}\psi_f \sin \theta + i_b L\right)$$

Then

$$T = \left(\frac{M\psi_f}{L_f\psi_0}\right)(i_a \cos \theta - i_b \sin \theta) \qquad (2)$$

Expanding this equation and neglecting all θ_Δ^2 terms because they are small for θ_Δ less than 15 degrees as assumed, and keeping impedances in ohms:

$$T = \left(\frac{M\psi_f}{L_f\psi_0}\right)^2 \frac{\psi_0}{I_0}\Bigg[\left\{\frac{\omega_s\gamma_s}{Z_s^2}\right\} + \left\{\frac{(\omega_\Delta+\omega_s)\gamma_{\Delta+}}{(Z_{\Delta+})^2} +\right.$$

$$\left.\frac{(\omega_\Delta-\omega_s)\gamma_{\Delta-}}{(Z_{\Delta-})^2}\right\}\frac{\theta_\Delta}{2} \cos \omega_\Delta t + \left\{\frac{(\omega_\Delta+\omega_s)X_{\Delta+}}{(Z_{\Delta+})^2} +\right.$$

$$\left.\frac{(\omega_\Delta-\omega_s)X_{\Delta-}}{(Z_{\Delta-})^2} - \frac{2\omega_s X_s}{(Z_s)^2}\right\}\frac{\theta_\Delta}{2} \sin \omega_\Delta t \Bigg\} \Bigg] \qquad (3)$$

Using per-unit impedances, and using the symbols s and Δ to represent the per-unit slip frequency and forced frequency respectively, the torque may be written in per-unit notation:

$$T = (E_d')^2\left[\frac{\frac{\gamma_s}{s}}{\left(\frac{\gamma_s}{s}\right)^2 + (X_s)^2}\right] + (E_d')^2 \times$$

$$\left[\frac{\frac{\gamma_{\Delta+}}{\Delta+s}}{\left(\frac{\gamma_{\Delta+}}{\Delta+s}\right)^2 + (X_{\Delta+})^2} + \frac{\frac{\gamma_{\Delta-}}{\Delta-s}}{\left(\frac{\gamma_{\Delta-}}{\Delta-s}\right)^2 + (X_{\Delta-})^2}\right] \times$$

$$\frac{\theta_\Delta}{2} \cos \omega_\Delta t + (E_d')^2\left[\frac{X_{\Delta+}}{\left(\frac{\gamma_{\Delta+}}{\Delta+s}\right)^2 + (X_{\Delta+})^2} +\right.$$

$$\left.\frac{X_{\Delta-}}{\left(\frac{\gamma_{\Delta-}}{\Delta-s}\right)^2 + (X_{\Delta-})^2} - \frac{2X_s}{\left(\frac{\gamma_s}{s}\right)^2 + (X_s)_2}\right]\frac{\theta_\Delta}{2} \sin \omega_\Delta t$$

$$(4)$$

In this equation, E_d' is the per-unit voltage proportional to $\frac{M\psi_f}{L_f}$, the flux which would link the armature if the circuit were opened and constant field flux, ψ_f maintained. In dealing with transient phenomena, this voltage would be called the voltage back of transient reactance.

From these torque equations, it is apparent that there is a steady torque dependent only on the average slip, s, and two alternating components, the $\sin \omega_\Delta t$ and $\cos \omega_\Delta t$ terms. The amplitudes of these alternating components are a function of the two frequencies $\Delta+s$ and $\Delta-s$. The sine term is in phase with, but opposed to the displacement and is, therefore, analogous to a weak mechanical spring connecting the two members. The magnitude of this spring constant is simply:

$$\frac{P(E_d')^2}{4}\left[\frac{X_{\Delta+}}{\left(\frac{\gamma_{\Delta+}}{\Delta+s}\right)^2 + (X_{\Delta+})^2} + \frac{X_{\Delta-}}{\left(\frac{\gamma_{\Delta-}}{\Delta-s}\right)^2 + (X_{\Delta-})^2} - \frac{2X_s}{\left(\frac{\gamma_s}{s}\right)^2 + X_s^2}\right]T_0$$

Where P is the number of poles in the coupling and T_0 is rated torque. If T_0 is in pound-feet, the constant is in pound-feet per radian.

The cosine term is a torque in phase with the alternating component of the velocity, and is analogous to mechanical velocity damping. The damping coefficient is:

$$\frac{P(E_d')^2}{4\omega_\Delta}\left[\frac{\left(\frac{\gamma_{\Delta+}}{\Delta+s}\right)}{\left(\frac{\gamma_{\Delta+}}{\Delta+s}\right)^2 + (X_{\Delta+})^2} + \frac{\left(\frac{\gamma_{\Delta-}}{\Delta-s}\right)}{\left(\frac{\gamma_{\Delta-}}{\Delta-s}\right)^2 + (X_{\Delta-})^2}\right]T_0$$

If T_0 is in pound-feet, the coefficient is in pound-feet per radian per second.

From the torque equation (2), it is seen that the pulsating components result from the action of the quadrature axis components of current ($i_a \sin \theta - i_b \cos \theta$). In order to simplify the derivation, the direct and quadrature axis reactances were assumed equal, but if they differ appreciably, the quadrature axis value should be used. If there are damping circuits on the field poles other than the field winding, they must be considered as affecting the reactance at the high frequencies.

Appendix B

Influence of the Electric Coupling on the Torsional Vibrations of the Propelling Drive

An important function of the electric coupling is to limit the transmission of torsional vibration from the engine to the gear. In the information published about electric couplings, it has often been stated that the electric coupling transmits only torques proportional to the slip, and therefore from the standpoint of torsional vibration separates the two systems on each side of it completely. As demonstrated in appendix *A*, this is not strictly true as the coupling acts as an elastic member having a spring constant which is a function of the frequency of the applied torque. It is zero at zero frequency and approaches a maximum value as the frequency increases. When a pulsating torque is applied to the coupling, a certain amount of energy is dissipated in the coupling. This energy acts as damping. For low frequencies up to one cycle per second, it is constant and equal to the torque normally produced in the coupling at normal slip, and then decreases rapidly as the frequency increases, being approximately inversely proportional to the frequency.

The electric coupling being located near the node of the vibration in the crankshaft, the damping in the coupling has very little influence on the amplitude of vibration in the engine. The damping in the coupling will be very effective in limiting the amplitude of low-frequency vibrations originating in the propeller if the nodes are such that large relative motions are produced in the coupling.

On high-speed Diesel engines, the low spring constant of the electric coupling has practically no influence on the natural period of torsional vibrations of the engine proper. Due to the small mass of the inner part of the electric coupling mounted on a very rigid crankshaft, this natural period is very high and only the critical speeds of high orders are in the operating range of the engine. Only an inappreciable part of these torque harmonics is transmitted through the coupling to the gears.

The effect of the spring constant of the electric coupling on the complete propelling drive is to produce a natural period of vibration of low frequency which might be in the range of the frequency of the torque impulses produced by the propeller blades cutting the wake of the ship. Usually, due to the large damping produced in the propeller, the vibrations thus produced are not dangerous unless they occur at the normal operating speed of the propeller. However, a thorough analysis of the complete propelling drive is advisable, making allowance for the spring constant of the electric coupling, to avoid any possibility of trouble.

Enclosed Spark Gaps

WM. E. BERKEY
MEMBER AIEE

Synopsis: Ionizing radiation has been discovered to be present in spark gaps of the type commonly used in commercial lightning arresters for the last 15 years. This radiation is emitted from discharges near the insulator-electrode contacts, when impulse voltage is applied to the gap. Ionization is produced by the absorption of this radiation in the spark gap. This effectively reduces the time lag of breakdown. The presence of this radiation explains why higher impulse breakdown voltages are obtained with a sphere gap in the dark than with a lightning-arrester spark gap with porcelain spacer. The radiation effect observed here is similar to that investigated by Wynn-Williams in the three-point gap. This paper tells of experiments performed to determine the reason for the low impulse ratios observed with rutile-spacer spark gaps. The results of this study explain the reason for the low impulse ratio of the "quench gap" and the "ionization gap" utilized in lightning arresters. This new information aids in understanding why low impulse ratios are obtained in high-voltage lightning-arrester spark gaps.

THIS PAPER describes experimental work which revealed a hitherto unrecognized, important factor responsible for the low impulse breakdown voltage found for short enclosed spark gaps such as are commonly used in lightning arresters. To obtain a low impulse ratio it has long been known that some form of ionizing radiation must be present.[1-4] In lightning-arrester spark gaps this radiation is emitted from subsidiary discharges discovered to exist between the electrodes and the insulating spacer, accompanying the dielectric displacement current. The intensity of this radiation may be expected to be proportional to the dielectric displacement current so that spark gaps with spacers of higher-dielectric-constant material, such as rutile,* give lower impulse ratios. This paper describes experiments made to study the interesting breakdown results obtained with rutile-spacer gaps. These tests led to the view that in lightning-arrester spark gaps the spark lag is reduced by radiation emitted from the region of the contact junctions between the insulator and metal electrode. Practical application of this work has been made in the design of lightning-arrester spark gaps by utilizing common insulating materials with intensified radiation means.

Electrical Tests

The test circuit of figure 1 is commonly used for impulse tests on spark gaps. A capacitor bank, C, is charged to 60 kv, just below the breakdown potential of the double gap, G_1, G_2. The breakdown of G_1, G_2, is synchronized with the measuring circuits by means of a timed impulse applied to the middle electrode. The rate of increase of voltage over the test gap is determined by the circuit constants C, L_1, and R_1. After the breakdown L_2 and R_2 assist in regulating the magnitude and wave shape of the surge current. Breakdown potentials are reduced by a tapped noninductive resistor, R_m, for voltage measurements by a cathode-ray oscillograph. All impulse breakdowns were made on a front-of-wave-test in which the surge increased at the average rate of 50 kv per microsecond. This rate of rise is recommended by AIEE Standards No. 28 for arresters of six-kilovolt and under rating. Sixty-cycle breakdown tests were taken with a testing transformer having a calibrated third winding and an induction regulator in the low-voltage winding. In approaching the breakdown voltage the rate of increase of 60-cycle voltages controlled by the regulator is reduced so that if the breakdown lag is long, the time of voltage application is also comparatively long. Experiments have shown a small dependence of the 60-cycle breakdown upon radiation, particularly with polished electrode gaps. However, for the purpose of this paper comparisons are based on the measured 60-cycle breakdown values rather than the true d-c breakdown which is more difficult to obtain.

The procedure in testing a gap was to record eight impulse-breakdown tests at ten-second intervals immediately followed by eight 60-cycle breakdown measurements taken consecutively. The average impulse-breakdown value divided by the average 60-cycle crest breakdown determines the impulse ratio. The impulse ratio is used to compare gaps because of its lesser dependence on small differences in gap spacing. A rough indication of the accuracy on repetition of a gap is obtained by expressing in per cent the lowest and highest readings in the series of eight breakdowns as a fraction of the average value. The column in table I under the heading maximum and minimum consistency compares the various gaps in this way.

A typical enclosed spark gap, figure 2, has a disk and a shaped brass electrode separated by an insulating-ring spacer which completely surrounds the sparking regions. The breakdown characteristics of this gap with the porcelain spacer are listed in table I, line A. When rutile ceramic was substituted for porcelain as the spacer material, the breakdown values measured are given in table I, line B. The main value of the rutile spacer previously anticipated was an improvement in voltage distribution over individual gaps in a multigap arrester. The lower im-

D	1.65 × 10^{-6} g radium, plain porcelain	8	8.85	7.35	1.20	105	95	100	98

pulse breakdown obtained with rutile-spacer gaps was so surprising that an investigation was made of this phenomenon.

Rutile

Rutile is a common mineral and is one of the three crystalline forms of titanium dioxide. Powdered rutile can be molded and fired with or without the addition of bonding materials such as china clay. The important difference between rutile ceramic and porcelain is the high dielectric constant of the rutile ceramic. A dielectric constant of 80 to 100 has been measured for rutile ceramics used as spacer materials. Rutile retains its high dielectric constant at frequencies of 10^6 cycles per second.

Electrical discharges appeared at he spacer-electrode contacts during the breakdown tests. This contact voltage is illustrated in figure 3 where under similar conditions higher gradients exist over the air space when a rutile spacer is used. When highly conducting metal films were placed over the rutile spacer-electrode contact areas no change in impulse ratio resulted. Metal films on porcelain spacer contacts lowered the impulse ratio materially as indicated in line *C* of table I.

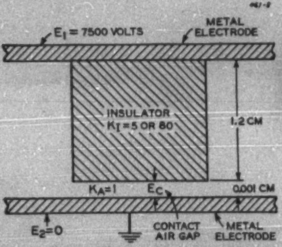

Figure 3. High gradients on assumed-contact air gap with porcelain and rutile spacers

Insulator	K_I(SIC)	E_c(Volts)	Gradient(Kv/Cm)
Porcelain	5	31	31
Rutile	80	470	470

The observed phenomenon with the rutile spacer gaps is similar to the effect of radiations from radium[5,6,7] and ultraviolet radiation[5,8] on the breakdown of spark gaps. Tests were made to see if the rutile contained enough radioactive materials to cause this improvement in impulse breakdown. The discharge rate of an electroscope was measured in room air, in close proximity to a rutile ceramic spacer, and with 1.65×10^{-6} gram of radium on a brass disk two centimeters from the collecting plate. The corresponding discharge rates were:

1. Air — 0.025 centimeter per minute
2. Rutile — 0.038 centimeter per minute
3. 1.65×10^{-6} grams radium — 150 centimeters per minute

A plain porcelain-spacer gap was tested with the radium-treated disk used in the electroscope tests and found to have a low impulse ratio of 1.2, table I, line *D*. It was concluded that the radioactive impurities in the rutile do not exist in sufficient quantities to cause the observed phenomena.

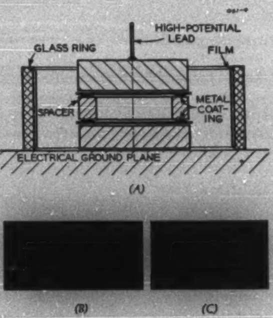

Figure 4. Dark-room tests

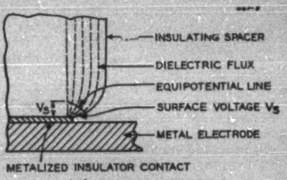
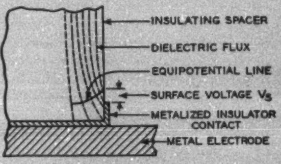
The possibility of the insulating surface emitting a radiation when electrically stressed was suggested and tests were made to see if such radiations were present. A rutile ceramic spacer with sprayed lead contacts was dipped into hot liquid ceresin wax, then cooled so that the entire surface of the spacer was coated with wax. The lead contacts on the rutile spacer were then scraped to remove the wax enough to make good contacts with the metal electrodes. In this scraping it is probable that some of the high-dielectric-constant spacer was exposed in the contact region. A low impulse ratio was obtained with the spacer insulating surfaces covered with ceresin wax. It, therefore, seems improbable that radiation from a stressed insulating surface causes the observed effect.

Barrier Tests

An attempt was made to interpose a barrier between the spacer-electrode junction and the central sparking region, by placing a loose fish-paper cylinder within the spark gap. At first low impulse voltages were obtained, but after changing the paper cylinder to a telescope construction, which was really light-tight, a high impulse ratio was obtained. When a $^1/_{64}$-inch-diameter hole was drilled through the otherwise opaque barrier, the impulse ratio was lowered.



(A) RECESSED CONTACT



(B) OVERLAPPED CONTACT

Figure 5. Potential over insulator surface near metalized contacts

Additional tests were made with picein wax covering the rutile spacer-electrode contact junctions on the inside of the spacer. When both of the electrode-insulator contact regions were covered with wax, high impulse ratios resulted. With only one contact region waxed, low impulse ratios were obtained. A contact layer of sprayed metal was brought up the inside of the rutile spacer and the contact regions waxed but with a small ring of exposed lead extending beyond the wax. Tests showed low impulse ratios when the lead film was exposed.

Dark-Room Tests

A bare X-ray film was located around a rutile spacer with sprayed lead contacts and two disk electrodes as shown in figure 4*A*. No blackening appeared when this gap was energized at 7,500 volts, 60-cycle frequency, for several hours. One hundred short-time chopped surge waves of ten kilovolts crest gave no trace of radiation on the film. When the gap of figure 4*A* was excited to 8,000 volts crest at 540 kilocycles for one hour the X-ray film obtained is reproduced in figure 4*B*. The whole film was diffusely blackened but two intensely blackened lines appeared as a result of radiation from the contacts. A picture of the contact discharges was made with Zeiss camera (approximately *f*5) with a two-minute exposure in a dark room using the fastest available commercial film. The contact discharges were greatly amplified by increasing the voltage to just under the insulator flashover value. The picture in figure 4*C* shows some indication of the localized nature of the contact discharges. One flashover took place during the exposure and is visible in the picture. The two bands of light in the picture are the result of several points of light from contact discharges that wandered around irregularly on the periphery of the rutile spacer at the lead-sprayed film outside edges.

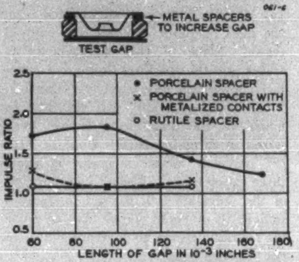


Figure 6. Variation in impulse ratio obtained by increasing gap distance while maintaining constant dielectric thickness

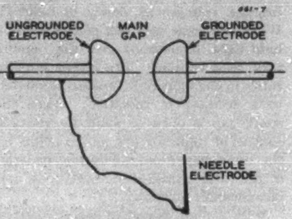

Figure 7. Three-point spark gap

Radiation From Contact Discharges

It is now obvious that the lower impulse-breakdown values obtained by the use of rutile spacers are due to a radiation in the gap coming from localized electric discharges at or near the inside contact junctions of the insulator and electrode. The radiation is present in abundant quantities to produce the effect through a $^1/_{64}$-inch-diameter hole. The discharges are attributed to stress concentrations and are present with highly conducting metal contact films. Two ways of producing stress concentrations with typical spacer shapes are shown in figure 5. It is not necessary to postulate imperfections in the surface of the dielectric to explain high air gradients. A metal contact film on the rutile spacer reduced the visible radiation intensity so that the contact discharges could not be seen in a dark room with careful observation under normal gap stress. Under this reduced visible intensity the impulse ratio was equally low. In the case of porcelain spacers the lead contact films definitely lowered the impulse ratio. This is attributed to the more favorable location of the radiation source on the porcelain.

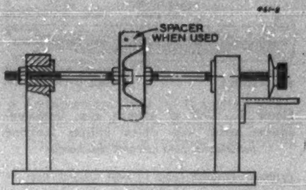

Figure 8. Externally supported spark gaps

That porcelain spacers may be made to radiate with greater intensity so as to lower still further the impulse ratio was proved by testing the porcelain gap at increased gap spacings which effectively increased the working stress of the porcelain. In the curves of figure 6 are plotted the impulse ratio as a function of the gap spacing where the gap spacing was increased by the addition of metal-ring spacers on top of the various insulating spacers. At about three times the normal gradient the plain porcelain spacer gap has an impulse ratio of 1.2.

The Three-Point Spark Gap

The impulse breakdown potential of a spark gap can be lowered by the three-point effect first explained by C. E. Wynn-Williams[9] in 1926. A typical three-point gap is reproduced in figure 7. When the sharp point of the needle was placed within six centimeters of the ungrounded electrode and electrically connected to it so that it was "visible" to the gap, a lower surge breakdown voltage was obtained. All barriers when placed in front of the point neutralized this effect except a specially prepared thin celluloid film. The effect was obtained in a dark room where no discharge could be seen to pass

Table II. Tests With Electrodes Supported Externally—Figure 8

Spacer	Electrodes	Gap (Mm)	Surge Breakdown (Kv)	60-Cycle Breakdown (Kv)	Impulse Ratio	Average Surge Gradient (Kv/Cm)	Average 60-Cycle Gradient (Kv/Cm)
None—open to room	Brass disk and shaped	1.65	14.5	8.84	1.64	88	53.5

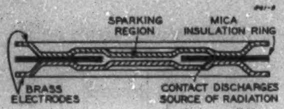

Figure 9. Unit of quench gap, lightning-arrester spark gap which utilizes ionizing radiations from contact discharges

Average impulse ratio of unit quench gap = 1.05

from the needle point to an electrode. His conclusions were that:

"1. Before the three-point phenomenon can be obtained some form of discharge, silent or spark, must be 'visible' from the main gap and within a certain distance of it.

"2. The phenomenon is obtained in the absence of:

"(a). Disturbance of the electric field near the main gap and

"(b). The passage of ions from the pilot discharge into the main gap.

"3. A radiation is emitted by the pilot discharge which can ionize the gas in the main gap.

"4. When this radiation is prevented from reaching the main gap the usual three-point effect is not obtained.

"5. The three-point effect is still produced when the electrodes are so shielded as to prevent any photoelectric effects...

"6. The observed properties of this radiation seem to establish the limits of its wave length as being approximately 13 to 1,000 angstroms, and they coincide to a large extent with the corresponding properties of *entladungstrahlen*."

As these conclusions so thoroughly explain the rutile-spacer spark-gap tests, it seems safe to conclude the same phenomena must be present in both cases.

Recent Work

H. Rather[10] has measured the absorption coefficient of similar radiation from a spark discharge. He believes the gas-ionizing radiation to be between the limits of 800 to 1,000 angstroms. By means of a Wilson cloud-chamber apparatus he has measured and extrapolated the absorption coefficient of the effective radiation from sparks to be $\mu=2$ for air, $\mu=0.8$ for hydrogen, and $\mu=5$ for oxygen, at 760-millimeter pressure.

Mounted-Electrode Tests

To observe the performance of a gap without short insulating spacers the disk and shaped electrodes were mounted on an adjustable micrometer spark gap as shown in figure 8. The electrode sparking surfaces were first polished, cleaned, and then roughened with fine alundum paper. The roughening process was repeated before each set of tests. The gap spacing was set equal to that of the porcelain gap of figure 2, and tested with the electrodes open to room air. The impulse ratio measured was 1.64 with 60-cycle and impulse voltages as shown in table II. When the same gap was placed inside a light-tight maplewood box the impulse ratio rose to 1.87. The higher impulse ratios in the light-tight box are attributed to a decrease of radiation. When the spark gap is open to room air, possible sources of radiation are corona points on the surge generator, radioactive material in the room, atmospheric radiations, and incandescent filaments.

With a plain porcelain spacer inserted between the electrodes of figure 8, the impulse ratio measured was 1.72. As the porcelain spacer makes the gap relatively light-tight some radiation must be present normally in the plain porcelain gap. The lower breakdown gradients recorded in table II for this test are added evidence of radiation. When a sprayed-lead porcelain spacer was tested in the same gap structure the impulse ratio was 1.36. This low value is attributed to a more favorable location of the radiation present in the porcelain-spacer gap. A leaded rutile spacer in the same gap structure gave an impulse ratio of 1.07. The breakdown gradients are low, indicating a greatly increased intensity of radiation.

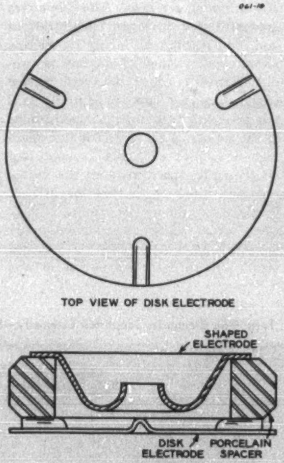

Figure 10. "Ionization" gap

Average impulse ratio of single ionization gap = 1.2

Two 3.8-centimeter spherical electrodes were mounted in the micrometer support and tested open to the room and in the dark box. The results listed in table II show a similar increase in impulse ratio for spherical electrodes in the light-tight box.

Applications

A single unit of the "quench gap" construction[11] is shown in figure 9. In this gap effective radiations are emitted from the mica insulator and electrode-contact region. Some of this radiation penetrates into the sparking region and effectively lowers the time lag of breakdown.

In the "ionization" gap sketched in figure 10 the disk electrode has been raised in three locations. Contact with the porcelain spacer is made on these three raised lands. The air in the region of the porcelain-disk contact is stressed sufficiently on rapid voltage rises to cause the sparking region to be irradiated as in the "quench gap."

Conclusions

The impulse ratio of spark gaps with spacings of between one and two millimeters depends upon the radiation present in the gap. An effective radiation is present in the usual porcelain-enclosed gap used in lightning arresters. This radiation is emitted from electrical discharges at the insulator-electrode junctions. A high-dielectric-constant spacer gives low impulse ratios, probably because the intensity of the effective radiation is proportional to the displacement current in the insulator. The wave length of the most effective part of a similar radiation was determined by Wynn-Williams in a study of the three-point spark gap as lying between 13 and 1,000 angstroms. Experiments in this region of the soft X-ray spectrum are difficult due to rapid air absorption.

The discovery of this radiation in porcelain-enclosed spark gaps explains why porcelain space gaps have lower impulse ratios than plain spark gaps of the same spacing in the dark. The results of this study fully explain the reasons for the low impulse ratios obtained in the "quench gap" and the "ionizing gap" which are both utilized in commercial lightning arresters.

Water Solution in High-Voltage Dielectric Liquids

F. M. CLARK
ASSOCIATE AIEE

IT HAS long been recognized by the practical engineer responsible for the proper maintenance of high-voltage oil-filled electrical equipment that water constitutes one of the chief and in some instances the only serious threat to successful service. However, consideration of the dangers presented by water during the operation of high-voltage machines must not be limited to a study of the relation between the dielectric strength and the water content of the insulating liquid used. For successful operation, the cellulosic insulation must be maintained in a dry condition. Water in such dielectrics leads ultimately to insulation failure. One of the first lines of defense against this disastrous result is the adequate drying of the solid dielectric in the factory manufacture of the equipment. Just as important, however, is the clear recognition that cellulosic insulation may be brought to a hazardous condition in service by water absorption from the surrounding atmosphere through the insulating liquid. The sorption of moisture by cellulosic insulation in this manner is of importance to all types of liquid-treated electrical apparatus but is of especial importance to liquid-cooled transformers in which the circulation of the liquid, carefully factored into the design for cooling purposes, so effectively presents a continuous supply of dissolved moisture to the hygroscopic insulation of the windings.

The dielectric-strength test of insulating liquids has long been accepted as an adequate protection against dielectric deterioration produced by water, but such a test as used in practice gives no adequate protection against the insidious penetration of water and its sorption by the cellulosic insulation. The practical dielectric strength represents the summation of many deteriorating effects, including the effect of fibers, dust, and other suspended or dissolved materials. The effect of these materials becomes greatly pronounced in the presence of water[1–4] and their prevalence in normal commercial practice has necessitated the establishment of dielectric-strength standards of such value that dissolved moisture may unsuspectedly be present in an amount which, because of its continuous transfer to the liquid-immersed cellulose insulation, may be sufficiently large seriously to affect the insulating properties of the latter and to present a dangerous condition for commercial use.

A Laboratory Test for Quantitatively Determining the Amount of Dissolved Water in Insulating Liquids

A number of test methods have been suggested for quantitatively determining the amount of water dissolved in mineral oil and other organic liquids.[5] The method adopted in this study has been a modification of the procedure suggested by Smith and Bryant,[6] the water content being expressed in parts per million by weight.

Dry nitrogen gas is bubbled through 500 to 1,000 grams of the carefully weighed insulating liquid at 130 degrees centigrade for a period of three hours. From the insulating liquid the nitrogen gas is led through two liquid-air traps where the entrained moisture is removed. The frozen condensate in the traps is dissolved in 25 cubic centimeters of dry acetone and slowly added to a cold acetyl chloride-pyridine mixture. In the preparation of this mixture, 10 cubic centimeters of acetyl chloride dissolved in dry benzene (118 grams per liter of solution) are contained in a dry 250-cubic centimeter glass-stoppered flask and cooled in an ice bath. Two cubic centimeters of dry pyridine are added dropwise to the acetyl chloride solution with continual shaking. A white precipitate of acetyl chloride-pyridine complex is formed.

After the slow addition of the acetone condensate solution to the ice-cold acetyl chloride-pyridine complex has been completed, the mixture is removed from the ice bath and allowed to stand at room temperature in diffused light (not in direct sunlight) for at least 15 minutes, but not more than 30 minutes, after which 20 cubic centimeters of dry ethyl alcohol are slowly added with continuous shaking. After a further standing at room temperature for five minutes, the solution is ready for titration with 0.5 *N* sodium hydroxide solution using phenolphthalein indicator.

A blank run is made simultaneously with the sample, using completely duplicate conditions except that no frozen distillate is added. This allows correction to be made for errors due to moisture inadvertently present.

In the actual application of water-testing procedures for insulating liquids, mineral oil is one of the more important insulating liquids tested. As is well

known, this material will be found in commercial apparatus in all stages of oxidation. This oxidation results in the formation of volatile acidic materials. Such products entrapped in the refrigerated tubes of the water-testing apparatus, will in themselves react with acetyl chloride or the sodium hydroxide used for the titration and produce erroneous results. For mineral transformer oils in normally good condition, the correction factor is negligible but for oils in the higher stages of oxidation a correction in the water content value must be applied. This correction corresponds to 7.3 parts per million of water content for each 1.0 milligram of potassium hydroxide per gram of oil used in the acidity titration.

The Solubility of Water in Dielectric Liquids

The amount of water dissolved by a liquid is a function of the chemical nature of the liquid itself and the conditions to which it is exposed. In the case of mineral insulating oil, the degree of refining and the previous oxidation to which it has been subjected are factors of real importance. Figure 1 illustrates the effect of refining treatment on the solubility of water in mineral transformer oils of low cold test.

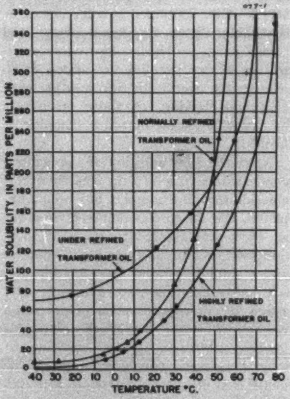

Figure 1. The solubility of water in mineral transformer oil and the effect of the refining treatment

In the use of mineral oils, oxidation effects must not be ignored when water-solubility problems are considered. Oxidation promotes the emulsification of water and leads to increased water solubility in the oil. Unless otherwise stated, only new, unoxidized mineral oils are used throughout this paper.

Synthetic, noninflammable, dielectric transformer liquids in commercial use are the chlorinated derivatives of the benzenoid hydrocarbons. These compounds are characterized by a high resistance to oxidation and are, therefore, not susceptible to changes in water solubility during use. This fact is demonstrated in the data of figure 2 which describe the solubility of water in new and used Pyranol.

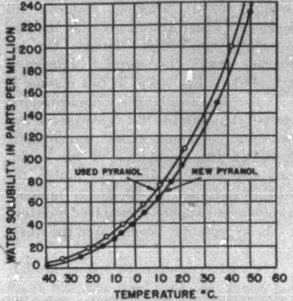

Figure 2. The solubility of water in transformer Pyranol

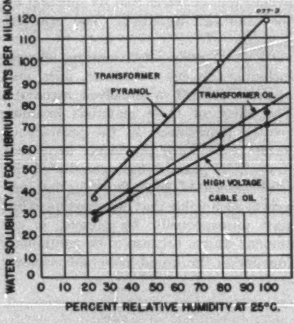

Figure 3. The maximum amount of water absorbed by transformer and cable insulating liquids exposed to humid air

The Hygroscopicity of Dielectric Liquids

The data presented in figures 1 and 2 are of interest and importance in indicating the limiting values of solubility beyond which water cannot accumulate in the liquid without visible cloud formation. Such values, however, give no indication of the sorptive ability of the liquid when exposed to less than water saturated atmospheres as in normal handling and use.

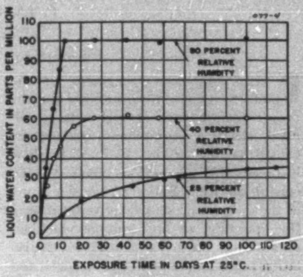

Figure 4. The absorption of water from humid air by transformer Pyranol

Figure 3 illustrates the water solubility in transformer liquids at equilibrium with air, the water content of which is expressed in the commonly used terms of relative humidity. Figure 3 also compares the water sorptive characteristics of a typical, American, Pirelli-type, high-voltage mineral cable oil. The comparative Saybolt Universal viscosity values at 37.8 degrees centigrade for the three liquids are:

Transformer Pyranol	55 seconds
Transformer mineral oil	58 seconds
Pirelli cable oil	100 seconds

The water equilibrium set up by an insulating liquid and the air with which it may be in contact is of importance in many commercial uses. In the handling of insulating liquids, however, it is also important to know the rate at which water is taken up by liquid. This is an extremely difficult practical problem since the speed with which a liquid approaches its water equilibrium condition is dependent on a large number of empirical factors, prominent among which is the intimacy of contact between the liquid and the humid atmosphere from which the water is taken. Large surface exposure produced by liquid circulation or other means accelerates water absorption. Figures 4 and 5 illustrate the rate of water absorption for mineral transformer oil and for transformer Pyranol exposed to air of different humidities. In this work the liquids were exposed in a quiescent state under the following conditions:

Volume of liquid, 7,500 cubic centimeters
Surface area exposed, 375 square centimeters
Liquid depth, 20 centimeters
Temperature of exposure, 25 degrees centigrade

The rate at which water is taken up by mineral oil is but little affected by those physical and chemical changes accompanying increased oil viscosity. This is illustrated in the data of figure 6 which compare three mineral oils of the Gulf Coast crude type, with viscosities which range from 58 seconds to 195 seconds Saybolt Universal at 37.8 degrees centigrade.

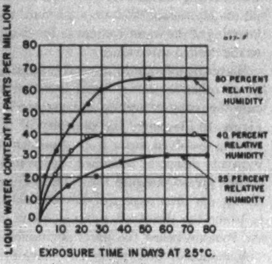

Figure 5. The absorption of water from humid air by mineral transformer oil

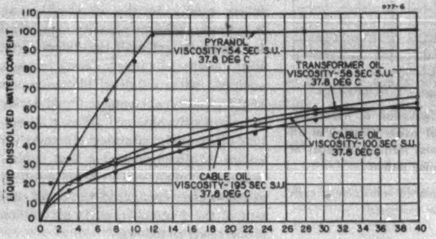

Figure 6. Comparing the water absorption by insulating liquids of different viscosity when exposed to humid air at 25 degrees centigrade

The Transmission of Water Through the Insulating Liquid and Its Sorption by the Cellulosic Insulation Immersed Therein

Cellulose has been described as a very hygroscopic material whose ability to absorb water is comparable to even the best of chemical desiccants.[7] It is, therefore, not unexpected to find that dry cellulose immersed in wet oil, reduces the water content of the latter. The rate at which the water is transferred from wet oil to the dry cellulose depends on factors similar to those which apply in the transfer of water from humid air to dry oil. Chief among these is the intimacy of contact between the cellulose fiber and the oil. Factors causing oil circulation, thus bringing a continuous supply of wet oil into contact with the paper insulation of a typical transformer-coil winding, will accelerate the moisture removal from the oil. Figure 7 illustrates the water transfer for one specific setup in which the dried cellulosic insulation was immersed in wet transformer liquid maintained without circulation at 25 degrees centigrade.

The data of figure 7 were obtained by humidifying the transformer liquid at 25 degrees centigrade. Kraft insulating paper (0.001 inch) was dried at 110 degrees centigrade under a pressure of 0.3 millimeter of mercury for 24 hours. The dry paper weighed 40 grams and was in the form of a cylindrical tube. The vacuum-dried paper, approximately 15 square feet in area, was immersed in 1 1/2 quarts of the wet liquid contained in a two-quart sealed, glass container which was allowed to stand without agitation. Samples of the liquid were withdrawn at frequent intervals for measurement of the dissolved water content.

Figure 7 is of value in indicating the rapidity with which dry cellulosic insulation will absorb moisture from the wet insulating liquid of a transformer. In obtaining the data of figure 7, it must be emphasized that there was a limited supply of water available that held by the insulating liquid. As the water was removed from the latter, its water content dropped until after about four days for the mineral transformer oil and 16 days for the transformer Pyranol an equilibrium was established between the water-in-liquid and water-in-cellulose condition. This equilibrium was substantially independent of the nature of the insulating liquid.

Figure 8 illustrates the water transfer occurring when wet insulating paper is immersed in dry transformer liquids. These data were obtained during a test run in which 40 grams of paper, prepared by exposure for 48 hours to air at 70 per cent relative humidity, 32 degrees centigrade, were immersed in the shape of a cylindrical tube in 1 1/2 quarts of dry insulating liquid, maintained throughout the test in a sealed container at 25 degrees centigrade. It is obvious from the data of figures 7 and 8 that the direction of water transfer, whether from liquid to cellulose or cellulose to liquid, is dependent on the relative moisture content of the materials involved.

In a sealed container, once the equilibrium condition is reached between the water content of the cellulose and that of the insulating liquid, it cannot be considered in an easily changed condition. This is illustrated in the data of figure 9. Here the 25-degrees-centigrade data of figure 7 for dry paper in wet mineral transformer oil and that of figure 8 for

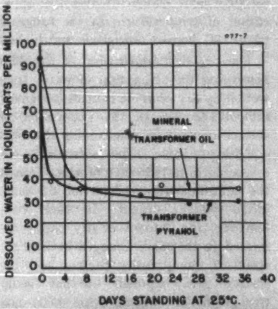

Figure 7. The dehydration of wet insulating liquids as a result of moisture absorption by dry cellulosic insulation immersed therein

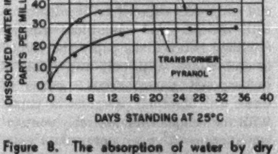

Figure 8. The absorption of water by dry insulating liquids in contact with cellulosic insulation previously exposed to humid air

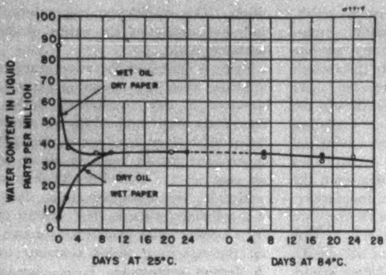

Figure 9. The characteristics of the moisture equilibrium set up between mineral transformer oil and the impregnated cellulose insulation

wet paper in dry mineral transformer oil are plotted together. After the common equilibrium has been established, each setup is heated from a 25- to an 84-degree-centigrade liquid temperature. The equilibrium is substantially unchanged. This behavior is of real importance in transformer practice for it indicates the danger which results when moisture is allowed to be dissolved by the insulating liquid. When once the moisture is absorbed by the impregnated cellulose, unless it be present in abnormally large amounts, it is released again only by drastic treatment which involves the application of temperatures in the range of 95 to 100 degrees centigrade and higher.

The practical application of the data describing the absorption of water from wet oil by dry cellulose is made extremely difficult because of the importance of surface contact in determining the final equilibrium value. This is demonstrated in a series of tests in each of which is used the same amount of oil having the same initial water content. In each test, however, the amount of dry paper immersed in the oil is changed both in respect to the quantity present and the surface area exposed. In one setup two grams of vacuum-dried 0.001-inch kraft paper were immersed in the oil so that the total surface area of 1.50 square feet was entirely bathed by the liquid. In a second setup, 40 grams of the same vacuum-dried paper with a total surface area of 30 square feet were assembled in a cylindrical-shaped roll and immersed in the oil so that only the outer roll surface and ends were exposed to direct contact with the oil. An equilibrium was established between the paper and the oil in each case. With only two grams of well-exposed paper, 0.0082 grams of water was absorbed per gram of paper. With the compact roll assembly containing 40 grams of paper, only 0.0014 gram of water was absorbed per gram of paper.

The Dehydration of Insulating Liquids

In the data already presented, it will be observed that in no instance has the presence of initially dry paper been able to reduce the water content of the dielectric liquid to zero. An equilibrium is ultimately set up which recalls the equilibrium generally recognized to exist between the water content of paper and of air. In the drying of cellulosic insulation, it is necessary to upset this equilibrium which is done in common practice by the use of heat and vacuum. The fact that an equilibrium also exists between water-in-liquid and water-in-cellulose indicates clearly that under some conditions as for example in the data of figure 8, the cellulose may impart water to the liquid. In like manner, an improperly dried blotter paper used in the filter-press treatment of the dielectric liquid, although removing suspended particles, may even lead to an increased oil-dissolved water content. It is further obvious that unless completely dried filter papers are successively supplied in the filtering treatment, the equilibrium ultimately established may prevent the lowering of the water content of the liquid to the desired safe value.

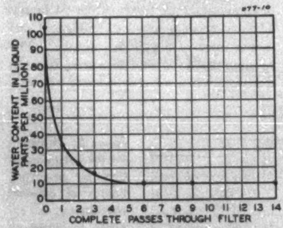

Figure 10. The dehydration of transformer Pyranol by means of paper filtration at 25 degrees centigrade with frequent changes of the filtering papers

Used papers were replaced at the time of each test value indicated

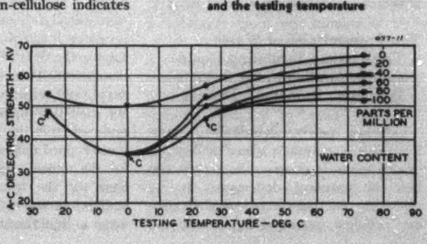
Water in solution in mineral insulating oil or other dielectric liquid is removed only by careful and severe treatment. Figure 10 illustrates the difficulty of removing dissolved water from transformer Pyranol using a standard seven-inch blotter press. Despite the extensive use of new, dry filter papers, it was impossible to lower the dissolved water content of the Pyranol below ten parts per million.

A modified filter press has been designed[8] which incorporates frames much deeper than those of the usual plate and frame press. These deeper frames give spaces which are filled with 80/300-mesh fullers earth. In the standard seven-inch press, sufficient capacity is provided for about one gallon of the fullers earth. With such a "fullers earth" press, equipped with well-dried blotter papers of the usual type, complete liquid drying is more easily obtained. Using 30 gallons of Pyranol containing 116 parts per million of dissolved water, and a filter containing fullers earth previously dried at 200 degrees centigrade, the water content of the Pyranol in parts per million is decreased as follows:

Initial water content	116
After one pass through filter	9
After one-half hour circulation through the filter	0

It is customary in some instances to

Figure 11. The rapidly applied a-c dielectric strength of mineral transformer oil as a function of its dissolved and suspended water content and the testing temperature



Points marked C indicate that the oil contains suspended as well as dissolved water. All dielectric strength tests were taken with a 0.20-inch gap setting degas mineral oil and other insulating liquids immediately after filter press or centrifuge treatment by passing the material through a vacuum chamber in the form of a thin film or spray. The assumption is usually made that such deaeration rapidly and effectively eliminates the dissolved water. This is not necessarily true. Mineral oil, even to the point where the dissolved air content is reduced to less than one per cent may still retain substantially large amounts of dissolved water. This was demonstrated in one form of commercial degassing equipment using mineral transformer oil containing 70 parts per million of water. After the degassing treatment, the oil still contained 46 parts per million of dissolved water.

A Practical Method for the Quantitative Estimation of Dissolved Water

A simple method for estimating the amount of water in solution in an insulating liquid involves the determination of its cloud point. Carefully carried out, the cloud point indicates that temperature below which the water in solution exceeds the saturation value of the liquid and separates with the formation of faint cloud. This water separation becomes pronounced and forms a turbid suspension in the liquid as the temperature is further lowered. This test procedure is limited to those materials free or substantially free from wax so that the formation of a cloud due to wax separation is avoided in the range of temperature of interest in dissolved-water determinations. Since, in general, the dielectric liquids in common use are of the naphthenic type of mineral oil or are synthetic benzenoid compounds free from wax separation on cooling, this limitation is not of serious significance.

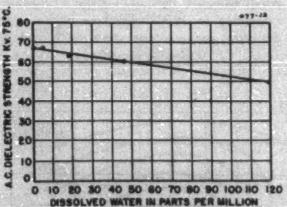


Figure 12. The effect of dissolved water on the rapidly applied a-c dielectric strength of mineral transformer oil tested at 75 degrees centigrade

All dielectric strength tests were taken with a 0.20-inch gap setting

The cloud-formation temperature relation to the liquid dissolved-water content is obtained from figure 1 for mineral transformer oil and from figure 2 for transformer Pyranol. The dissolved-water contents shown in these figures are those of the water-saturated condition for the corresponding temperatures. These temperatures are, therefore, the cloud-point values since further increase in water content or a further decrease in temperature results in the formation of a visible cloud.

The difficulty in the cloud-point test is that, except for the highest water contents, the test involves refrigeration with accompanying frost formation on the walls of the containing vessel and the necessity of protecting the liquid under test from water pick up due to frost formation on its surface. A suggested form of test apparatus utilizes a clear vacuum bottle within which the liquid under test, contained in a clear-glass stoppered tube, is cooled at a standardized rate in accordance with principles of the method of test for the cloud and pour point of mineral oils, described under designation *D*97-34 of the American Society for Testing Materials.

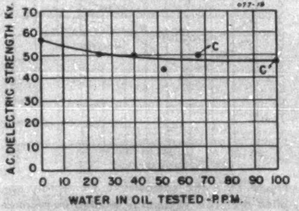

Figure 13. The rapidly applied a-c dielectric strength for mineral transformer oil tested at 25 degrees centigrade as a function of its dissolved and suspended water content

Points marked C indicate that the oil contains suspended as well as dissolved water. All dielectric strength tests were taken with a 0.20-inch gap setting

The Effect of Dissolved Water on the A-C Dielectric Strength of Insulating Liquids

Repeated researches have indicated that the dangerously low dielectric strengths normally attributed to the presence of water in commercial insulating liquids are to be associated as well with the accidental presence of suspended solids such as dust particles, fibers, and the like.[1-4] It is undoubtedly true that mineral oil or other insulating liquid may contain appreciable amounts of dissolved water and, in the absence of suspended impurities, still retain what is commercially regarded as a good dielectric strength. This results in the fact, already indicated, that the dielectric-strength test as commercially applied does not give good protection against the insidious penetration of moisture through the liquid to the hygroscopic cellulosic insulation immersed therein. Irrespective of its effect on the dielectric properties of the liquid, unlimited penetration of moisture and its sorption by the cellulose must be avoided if satisfactory commercial operation of high-voltage apparatus is to be obtained.

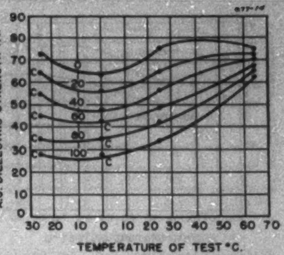

Figure 14. The effect of temperature and dissolved and suspended water in the a-c rapid applied dielectric strength of transformer Pyranol

Points marked C indicate that the oil contains suspended as well as dissolved water. The figures on the curves indicate the total water content of the liquid. All dielectric strength tests were taken with a 0.20-inch gap setting

Because of the unavoidable variation in water content during the handling and testing of an insulating liquid, it has been most convenient to determine the dielectric strength of the liquid for at least four water-content values covering the range of interest and from the smooth line (average) relation established, to select definite values of water content for comparison and further technical analysis. Thus, for example, the 75-degree-centigrade data of figure 11 are based on the smooth-line relation of figure 12 which describes the dielectric strength of mineral transformer oil at 75 degrees centigrade as a function of its dissolved-water content, the values indicated being experimentally determined. In general, the basic experimental data correlating the dielectric strength and the water content of the insulating

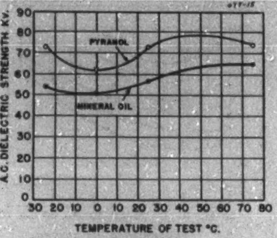

Figure 15. The comparative a-c rapidly applied dielectric strength of dry transformer Pyranol and dry mineral transformer oil

All dielectric strength tests were taken with a 0.20-inch gap setting

liquid are eliminated for reasons of brevity. The analyses which are shown are based on selected points taken from the smooth-line relation correlating the experimentally determined values.

The dielectric test results were obtained using brass electrodes meeting the requirements of the American Society for Testing Materials, designation *D*117-33. The gap distance used throughout was 0.20 inch. Temperatures recorded are the liquid temperature values at the time of test. In all instances, no dielectric-strength readings were made until the liquid had been at the testing temperature for several hours. The water-content values given include suspended as well as liquid dissolved moisture. The presence of suspended water is indicated.

The rapidly applied dielectric strength has been determined in accordance with American Society for Testing Materials, designation *D*117-36, in which the voltage is evenly raised to breakdown at the rate of three kilovolts per second.

To define adequately the effect of dissolved and suspended water on the dielectric strength of an insulating liquid, it becomes evident at once that the temperature of test must be carefully specified. Practically speaking, a wide range of testing temperatures must be covered for liquid treated insulations are often used in high-voltage dielectric practice specifically because of the stability of their dielectric properties over a wide range of operating temperatures. In these tests, temperatures from −25 to +75 degrees centigrade have been studied.

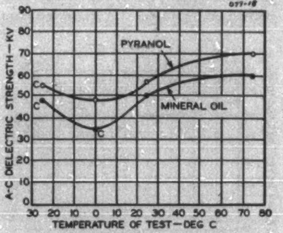

Figure 16. The comparative a-c rapidly applied dielectric strength of mineral transformer oil and transformer Pyranol, each containing 40 parts per million of dissolved water

Points marked C indicate that the oil contains suspended as well as dissolved water. All dielectric strength tests were taken with a 0.20-inch gap setting

It has been pointed out in a previous publication[8] that the dielectric strength of mineral insulating oil as affected by temperature varies from oil to oil. With some oils, notably the viscous cable oils, the dielectric strength falls with temperature increase above room temperature. With mineral oils of the transformer type, the dielectric strength increases to a maximum with temperature increase above room temperature. The dielectric strength-temperature relation has been considered to reflect the solubility characteristics of dissolved air. In this study of the dielectric strength of mineral oil as affected by the dissolved and suspended water content, available data are limited to the behavior of air-saturated mineral transformer oil prepared from Gulf Coast crude and having a viscosity at 37.8 degrees centigrade of approximately 58 seconds Saybolt Universal. With such an oil, the effect of temperature increase on the dielectric strength is a function of its water content. The dielectric strength increases most rapidly with temperature increase from 25 to 75 degrees centigrade when the water content of the oil is held at low value. This is illustrated in the data of figure 11.

In any study of the effect of water on the dielectric strength of mineral oil, difficulty is at once experienced because of water separation as the temperature is lowered. This limits the study of the effect of dissolved water to a narrow range of water contents as the lower temperatures are investigated. Thus, as is shown in figure 12, even with a water content as large as 120 parts per million, clear solutions are obtained at 75 degrees centigrade and the decrease in dielectric strength with increased water content is easily demonstrated. At 25 degrees centigrade, however, the limit of water solubility as indicated in figure 1 for

Figure 17. The rapidly applied direct-voltage dielectric strength of mineral transformer oil as affected by tem perature and its dissolved and suspended water content

Points marked C indicate that the oil contains suspended as well as dissolved water. All dielectric strength tests were taken with a 0.20-inch gap setting

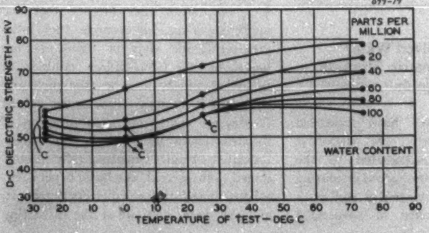

Figure 18. The rapidly applied direct-voltage dielectric strength of transformer Pyranol as affected by temperature and its content of dissolved and suspended water

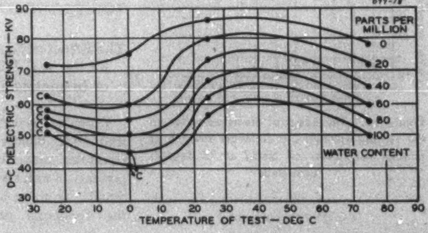
Points marked C indicate that the oil contains suspended as well as dissolved water. All dielectric strength tests were taken with a 0.20-inch gap setting



normally refined transformer oil is about 70 parts per million. The higher water contents of figure 11 are, therefore, cloudy suspensions. It is only with wet oil free from suspended water that a clear effect of dissolved water on the dielectric strength can be demonstrated. The dielectric strength for oil containing suspended water is independent of the water content within the limits explored (figure 13). For tests at lower temperatures similar results are obtained.

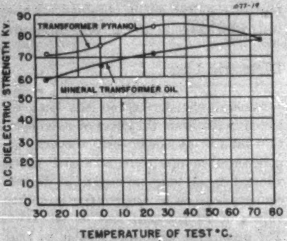


Figure 19. The comparative dielectric strength of dry mineral transformer oil and dry transformer Pyranol tested under direct-voltage application

All dielectric strength tests were taken with a 0.20-inch gap setting

Synthetic, noninflammable transformer liquids of the Pyranol type have already been described as possessing a maximum dielectric strength at about 50 degrees centigrade.[10] As illustrated in figure 14 this is true for such liquids only when containing small amounts of dissolved moisture. With increased water content the dielectric strength rises continuously with the increasing temperature of test.

Insulating liquids of the Pyranol type, as shown in figure 14, are characterized by a continually decreasing dielectric strength with increased water content. No abnormality in the relation is observed at the point of cloud formation, indicative of water separation from solution.

The Pyranol type of transformer insulating liquid in normally dry condition possesses a dielectric strength which is superior to that of mineral transformer oil. Figure 15 compares the dielectric strength of these two typical transformer liquids as affected by temperature when dry. Figure 16 compares the dielectric strengths of the two liquids each containing 40 parts per million of dissolved water.

The Effect of Dissolved Water on the D-C Dielectric Strength of Insulating Liquids

Under rapidly applied direct voltage, transformer insulating liquids behave in a manner similar to that already described for a-c breakdown. Figure 17 describes the d-c breakdown of mineral transformer oil as a function of temperature and water content. The general resemblance to the a-c breakdown values of figure 11 is marked. The effect of dissolved water is most clearly demonstrated in the 75-degree-centigrade tests. And again, as in the alternating-voltage breakdown, the formation of a cloud in the oil tends to obscure the effect of further water additions.

Figure 18 describes the d-c dielectric-strength characteristics of transformer Pyranol. As in the a-c breakdown data of figure 14, the effect of water content on the dielectric strength is marked.

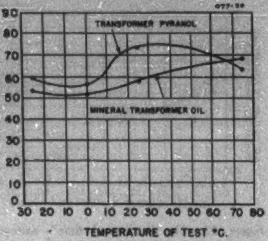

Figure 20. The comparative dielectric strength of mineral transformer oil and transformer Pyranol each containing 40 parts per million of dissolved and suspended water and each tested under rapidly applied direct-voltage application

All dielectric strength tests were taken with a 0.20-inch gap setting

Figures 19 and 20 compare the d-c breakdown characteristics of mineral transformer oil and transformer Pyranol. Figure 19 compares the materials in the dry condition. Figure 20 compares the materials each containing 40 parts per million of water. The dielectric strength of transformer Pyranol is generally higher than the dielectric strength of mineral transformer oil except at 75 degrees centigrade, at which temperature the two liquids appear of equivalent dielectric strength under direct-voltage tests.

The Time-Voltage Relation

The time-voltage characteristic applying to an insulating liquid is a property of difficult determination because of the sharp "knee" which is obtained in the relation at a relatively short time interval. That part of the time-voltage relation which parallels the time axis and which designates the voltage that can be

Figure 21. The time–alternating (effective) voltage relation for transformer Pyranol as affected by the dissolved and suspended water content

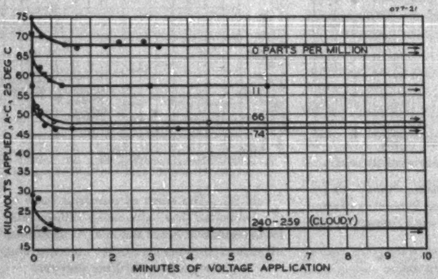

Figure 22. The time–alternating (effective) voltage relation for mineral transformer oil as affected by the dissolved water content

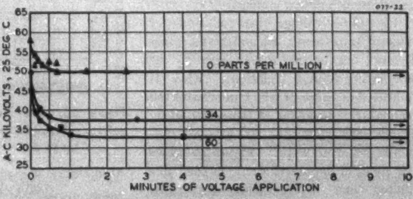
An arrow indicates that repeated applications of the voltage shown gave no dielectric breakdown within the time limitations of the test.

All dielectric-strength tests were taken with a 0.20-inch gap setting



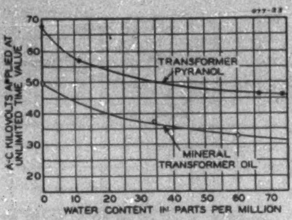


Figure 23. The "unlimited time" voltage value for transformer Pyranol and mineral transformer oil as affected by the water content of the liquid

All dielectric-strength tests were taken with a 0.20-inch gap setting

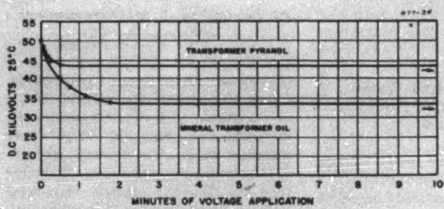

Figure 24. The time – direct-voltage relation for transformer Pyranol and mineral transformer oil each containing 60 parts per million of dissolved water

An arrow indicates that repeated applications of the voltage shown gave no dielectric breakdown within the time limitations of the test. All dielectric-strength tests were taken with a 0.20-inch gap setting

applied without fear of breakdown within the experimental time limit, is called the "unlimited time" value of voltage. In general, the maximum time allowed for breakdown in the work described has been limited to ten minutes. The electrodes used were duplicates of those employed in the rapidly applied test investigations and were spaced 0.20 inch apart. All tests were at 25 degrees centigrade. Both direct and alternating (effective) voltages have been studied.

Figures 21 and 22 describe the time-voltage (a-c) relation for transformer Pyranol and mineral transformer oil as affected by the dissolved and suspended water content. Figure 23 compares the effect of dissolved water on the "unlimited time" voltage values for mineral oil and Pyranol. The relations established are of marked similarity.

The direct-voltage–time relation for mineral transformer oil and transformer Pyranol bear strong resemblance to the alternating-voltage relation. This is indicated in figure 24 which illustrates the comparative behavior of these insulating liquids each containing 60 parts per million of dissolved water. Figure 25 shows the effect of dissolved water on the "unlimited time" direct voltage for transformer Pyranol over the range of water contents of practical interest.

The Relation of the Rapidly Applied to the "Unlimited Time" Breakdown Voltage

In the use of insulating liquids it is most convenient and reliable to gauge the dielectric strength by means of a carefully controlled rapidly applied alternating-voltage test. The determination of the "unlimited time" voltage is difficult and time consuming. For both transformer Pyranol and mineral transformer oil, the "unlimited time" voltage falls to approximately 70 per cent of the usual rapidly applied dielectric strength value as the water content of the liquid is increased at 25 degrees centigrade. The relation is illustrated in figure 26.

The D-C/A-C Ratio of Dielectric Strength

The relation between the rapidly applied d-c and the a-c (effective) dielectric strengths of mineral transformer oil and of transformer Pyranol has no fixed value. The ratio obtained for mineral transformer oil varies erratically between 0.89 and 1.58 as the temperature of test and the water content of the oil are changed. For transformer Pyranol, the range in d-c/a-c ratio value is between 0.89 and 1.37.

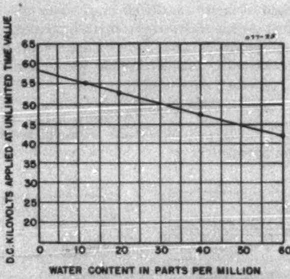

Figure 25. The "unlimited time" direct-voltage value of transformer Pyranol as affected by its dissolved water content

All dielectric strength tests were taken with a 0.20-inch gap setting

When the "unlimited time" voltage breakdown value is studied, a more consistent behavior of the d-c/a-c relation is observed. Figure 27 illustrates the ratio for transformer Pyranol using the "unlimited time" direct and alternating (effective) voltage values illustrated in figures 23 and 25. A ratio value linearly decreasing with the increased water content of the Pyranol is obtained. These tests were taken at 25 degrees centigrade.

Dielectric Loss

Mineral transformer oil has been selected to illustrate the effect of water solution on the dielectric loss. Several experimental setups were arranged which allowed the oil to be exposed at 25 degrees centigrade to air having relative humidity values of 24 per cent and 65 per cent. The apparatus used was similar to that already described under the paragraph entitled "The Hygroscopicity of Dielectric Liquids." Power factor and resistivity measurements were made at 25 degrees centigrade. The power-factor measurement was at 60 cycles under 3,000 volts. The resistivity was measured after the application of 500 volts direct current for one minute. The electrode gap setting in all cases was 0.10 inch.

Figure 28 illustrates the power-factor results obtained. From the dry-oil condition the power factor rises rapidly with increased water content to reach a maximum stable value at about 15 parts per million of dissolved water. Figure 29

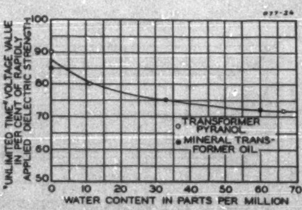

Figure 26. The effect of dissolved water on the "unlimited time" alternating-voltage value for transformer Pyranol and mineral transformer oil expressed in per cent of the corresponding rapidly applied dielectric strength

indicates a similar behavior for d-c resistivity measurements.

In considering the data of figures 28 and 29 it must be kept in mind that the oil tested was new oil uncontaminated by foreign materials or by oxidation products, the effect of which would necessarily be determined by their chemical and physical properties.

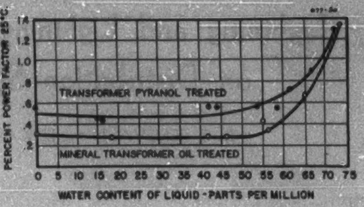

Figure 30. The power-factor characteristics of vacuum-dried kraft paper insulation as affected by water absorption after impregnation with transformer Pyranol and with mineral transformer oil

Cellulosic insulation is usually considered to be very susceptible to dielectric change caused by water. The presence of conducting salts and hygroscopic organic material serves to explain this marked susceptibility. Figure 30 describes the 30-degree-centigrade 60-cycle power-factor change in kraft-paper pads immersed in new mineral transformer oil and in new transformer Pyranol which are each exposed to humid air under conditions similar to those applying in the experimental setup of figures 28 and 29. The kraft-paper pads were originally well dried under a pressure about 0.3 millimeter of mercury at 100 degrees centigrade after which they were impregnated with the dry liquid. Although the data of figure 31 give no indication of the amount of moisture absorbed by the insulation, the test period covered several weeks and was sufficiently long for the insulation to reach an equilibrium with the water content of the surrounding liquid. Figure 30 leads to the conclusion that liquid-dissolved water does constitute a hazard to the successful maintenance of low-loss impregnated cellulose insulation. With new and unused insulating liquids, the 25-degree centigrade 60-cycle power factor of the impregnated cellulose insulation rises rapidly as the dissolved-water content of the impregnating liquid approaches and exceeds approximately 50 parts of dissolved water per million.

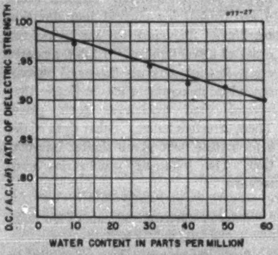

Figure 27. The 25-degree-centigrade "unlimited time" d-c/a-c (effective) voltage ratio of dielectric strength for transformer Pyranol as affected by its dissolved water content

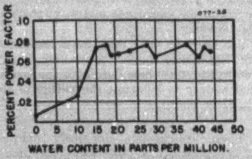

Figure 28. The effect of dissolved moisture on the 60-cycle power factor of mineral transformer oil measured at 25 degrees centigrade

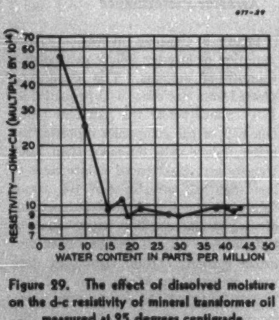

Figure 29. The effect of dissolved moisture on the d-c resistivity of mineral transformer oil measured at 25 degrees centigrade

The effect on the power factor of liquid-immersed cellulosic insulation produced by moisture absorption becomes more pronounced as the temperature is raised above 50 degrees centigrade. This is illustrated in the data of figure 31. In this instance, carefully dried and impregnated kraft-paper insulating pads were immersed for 21 days at 70 degrees centigrade in transformer Pyranol, over the surface of which was maintained a layer of water about one-half inch deep. The sorption of water by the treated cellulose greatly increases the power factor at the higher testing temperatures.

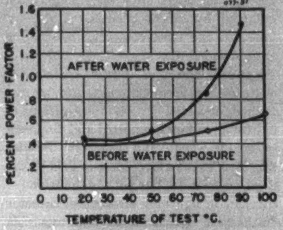

Figure 31. The effect of water absorption on the power factor temperature relation for transformer-Pyranol-impregnated kraft-paper insulation

Lightning and Lightning Protection on Distribution Systems

R. C. BERGVALL
ASSOCIATE AIEE

EDWARD BECK
MEMBER AIEE

THE CONCEPTIONS of lightning and of lightning discharge currents through arresters have been altered and enlarged by recent studies. Until not long ago the most complete information available on the magnitude and wave shape of lightning surges on electric systems has been that obtained by the cathode-ray oscillograph investigations of lightning voltages, reported and discussed before the AIEE,[1] and elsewhere. Besides this there exists a large mass of data on the crest magnitudes but not the durations of currents in lightning strokes and arrester discharges. Based on the data available two conclusions have been generally held: one, that in a small percentage of discharges, the currents may be high, perhaps 65,000 amperes or more; and two, that the total duration of the discharge might be of the order of 100 microseconds, but not much more. Lightning-arrester design was based principally upon these conclusions. Arresters available during the past six or eight years have in general been able to discharge high currents of the durations cited without damage. In the field, the over-all experience with such arresters has been good. Throughout the country the average failure rate of Autovalve distribution arresters manufactured during that period has been less than a quarter of one per cent per year. However, in rural locations in some parts of the country failure rates of three to four per cent have occurred. This is considered excessive. The variation in failure rates led to the suspicion, several years ago, that there are characteristics in arrester discharge currents that had not been taken into account and which are themselves influenced by such factors as lightning exposure, stroke characteristics, ground resistance, and system characteristics. It is true that to some extent the significance of the data may be obscured by failures from abnormal system voltages and by the performance of obsolete arresters, but these factors were not sufficiently weighty to explain the observations.

The purpose of this paper is to discuss the present state of our knowledge of this matter resulting from the observations and investigations of the authors and their colleagues. We do not propose to provide a complete answer at this time to the questions raised because insufficient field data exist. The authors hope that this paper will stimulate others to give the subject study. It is expected that a considerable volume of informative data will be available after another season's research with "fulchronographs," the recently developed surge wave recorders.

Inspection of Arresters

A systematic inspection of Autovalve arresters removed from service was undertaken several years ago by our associates. Arresters that had failed in service as well as arresters which had not were examined. A surge discharge of high crest or of appreciable duration leaves a distinctive mark on the series-gap electrodes. This serves as an indication of crest current and duration if not obscured by power current. Crest currents above 3,000 amperes of short duration (less than 100 microseconds) leave marks like splashes. A low current of a few hundred to a thousand amperes of long duration (1,000 or more microseconds) produces a small pit with definite evidence of burning. Currents of high amplitude and long duration cause local melting of metal. A calibration of the appearance of the surge tracks as related to current magnitude and duration has been made. Typical results are shown in figure 1*a*.

Comparisons of electrodes from arresters that had seen service were made with the laboratory calibrations. Figure 1*b* shows representative field electrodes. These are especially significant because all but number 5 came from arresters installed on a line struck by lightning while it was unenergized. There is thus no question of masking by power current even in the cases where the arresters failed. Typical currents of high crest and short duration appear in 1, 2, and 3. The crests are of the order of 50,000 amperes and the durations approximately 50 microseconds. Number 2 has additional marks indicating other surges of lower crests. The elements of these arresters were not injured. Records 4 and 5 are typical low-current long-duration markings. They indicate currents of the order of a few hundred to 1,000 amperes crest lasting several thousand microseconds; moreover they indicate that several such discharges took place. These arresters failed. Other data of the same nature have given similar information. The following conclusions were reached:

1. Arrester discharge currents of low magnitude and long duration occur.
2. Such discharges are more likely to cause arrester failure than very high currents of short duration.
3. As far as arresters in service are concerned, either type of discharge may occur independent of the other.
4. It is important that field data be collected on the magnitude and wave shape of the discharge currents that prevail and which arresters must meet for a reasonable life expectancy under severe conditions; and to correlate these data with the factors that appear to influence the nature of the discharge currents in service.

These conclusions definitely pointed to a revision of our thinking about lightning-arrester discharge currents. Other observed circumstances strengthen this opinion.

Statistical Data on Arrester Performance

Figure 2 gives an indication of the variation of arrester failure rates over a number of systems. This curve was plotted from statistical data presented by L. G. Smith before the AIEE in 1937.[2] One-half of the companies reporting arrester failure data on more than 1,000 transformers experienced failure rates of less than 0.3 arrester per 100 transformers, but a few reported failure rates of two or more. The paper shows a ratio of four to one between rural and urban systems. Other significant data were presented by McEachron and McMorris in 1938.[3] Many crest measurements without duration of arrester dis-

Arresters of 1, 2, and 3 were electrically undamaged. Arresters of 4 and 5 failed

charge currents are reported there and the occurrence of arrester failures is apparently not related to their magnitudes or to their relative frequency of occurrence on different systems in different parts of the country. Figure 7 of that paper is of considerable interest. It compares the frequency of occurrence of crest currents of various magnitudes on two different systems. Although the Detroit data indicate a greater prevalence of high currents, the observed failures of arresters are higher in Georgia. Low currents occur more often in Georgia than in Detroit. McEachron and McMorris report that 68 per cent of the observed arrester failures took place in Georgia although only 34 per cent of all the records were obtained there.

Stroke Characteristics

Photographic studies of strokes by several investigators, for instance Schonland and Collens, and Walter, indicated the probability that strokes may not only be multiple but also may involve moderate or low-current components of considerable duration. Stekolnikov and Valeev[4] in 1936 made records of lightning currents to a captive balloon. A rotating klydonograph used by them indicated that the duration of current flow lay between 2,600 and 10,000 microseconds. McEachron's work on the Empire State Building[5] also gave evidence of this phenomenon. Last summer, Wagner and Beck[6] obtained a complete record of the current in a direct stroke to the Cathedral of Learning of the University of Pittsburgh which definitely showed both high short and low long components. The oscillograph studies on lines had not indicated that this occurred on systems, but the authors suspect that because of the sensitivity limitations of the cathode-ray oscillograph the low long component may have been present but not revealed.

There is definite evidence that the long low components will frequently, if not always, appear in strokes to tall conductors. It is probable that the characteristics of strokes to lines are different from those to high objects but there is sufficient evidence to be convincing that long-duration components appear also to some extent on lines when struck by lightning.

New Recording Instrument

The available measurements of stroke currents cannot be translated into arrester duty until a significant volume of wave-shape data on strokes and arrester discharges in the field has been collected. This had not been done for lack of a recording device sufficiently low in cost to be installed in considerable numbers. The invention of the fulchronograph by Wagner and McCann described by them in a contemporary paper has made the needed device available.

It is evident that crest currents only without the important factor of duration did not give a complete understanding of arrester duty. The work has been begun. In co-operation with a number of utilities, many fulchronographs were installed during the summer of 1939, and already a considerable number of records has been obtained.

The fulchronograms of discharges through arresters in service are not yet of the desired technical significance. No records have been obtained accompanied by arrester failure. Records falling toward the expected extremes of high current or of long duration have not been secured. They do indicate, however, that arresters sometimes are called upon to handle, and do so successfully, considerable blocks of current (figure 3) appreciably in excess of the existing AIEE standard test. The paucity of heavy surges is not unexpected, inasmuch as experience with fixed link records as well as with arresters indicates that harmless currents are much more frequent. Some typical fulchronograms are shown in figure 3. These are all records of discharge through individual phase legs of arresters. Numerous records have been made of discharges of less than 1,000 amperes and short duration.

The observations and tests discussed in the foregoing show that the occurrence of long-tailed moderate-current surges accounts for the abnormally high failure rates experienced in certain rural regions on the basis that in these regions arresters must discharge such surges more frequently. The ability of the De-ion protector such as is used in the *CSP* transformer, to handle currents of long duration probably accounts to a large extent for its low failure rate in service.

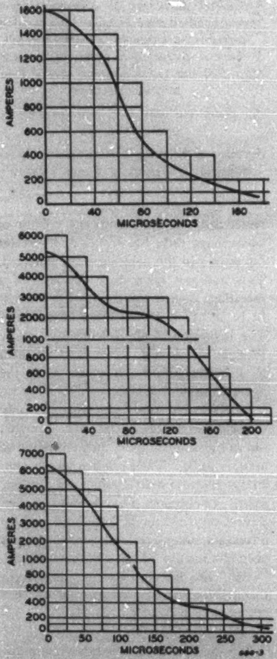

Figure 3. Typical records of discharge currents through single-phase legs of lightning arresters in service, obtained with the fulchronograph

Effect of System Characteristics

Low-current discharges through arresters are fairly common. This is demonstrated, for instance, by published data.[3] Figure 3 of the reference indicates that among 100 rural arrester installations, discharges of the following crest magnitudes (no data on duration) may be expected.

Amperes exceeding:	500	1,000	2,000	5,000	10,000	15,000
Discharges per year:	40	33	20	7	3	2

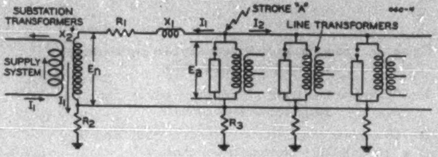
If the comparatively numerous low-current discharges through arresters were all or to a major extent of the long duration which might be expected from the observed stroke characteristics, laboratory tests on all types of distribution arresters would lead us to expect much higher arrester failure rates than those experienced and published.[2] Since many strokes evidently have these long low-current components there must be drainage effects present in many instances that relieve arresters installed on systems of some of this current.

Line flashovers from steep-front strokes to the line at points remote from arresters will by-pass a large proportion of the surge current. The effects of soil resistivity both on the degree of current drainage and perhaps on the character of the stroke itself may partly explain the difference in failure rates. In general, it has been found that where soil resistivity is high, arrester failures are more frequent. In addition to this, however, variations in arrester failure rates between locations resembling each other in insulation levels and soil resistivity point to another factor.

On grounded-neutral systems, both substation and distribution transformers are in parallel with the arresters and provide possible paths to ground for part of the current in long surges. A study was made of the current drainage characteristics of these shunt paths. The following discussion covers a typical example to illustrate the effects of system characteristics.

Figure 4. Surge-current drainage paths in parallel with distribution arresters

For I_1 see figure 5, and I_2 see figure 6



E_a—Arrester counter voltage

E_n—Alternating voltage to neutral

To use figure 5, calculate a-c short-circuit current at arrester nearest stroke with sufficient accuracy by using $R=(R_1+R_2)$ and $X=(X_1+X_2)$ (60 cycles), where X_1 is taken as 0.75 ohm per mile and X_2 is the substation transformer plus supply-system leakage reactance. Variation of R_3 through a 10–50 ohm range does not change I_1 appreciably

In figure 4 is shown a long single phase circuit with distribution transformers and arresters, fed by a substation transformer. A stroke to the first arrester will discharge initially through it and possibly also through adjacent arresters depending on the surge front. With a steep-front stroke close to, or a slow-front stroke remote from an arrester, line flashover will not occur and all of the stroke current is carried by the arrester or arresters discharging first. The stroke current flowing into the system is assumed, for purposes of calculation, to have a low-current component of 1,000 amperes of such length that it may be considered a direct current. For durations of 1,000 microseconds or more this is entirely justified. This current, discharging through the arrester, produces a voltage at the arrester terminals, which in turn is impressed on the system. The magnitude of the voltage is the counter voltage of the arrester corresponding to the discharge current. Laboratory tests (figure 11) show that the counter voltage of the Autovalve arrester under these conditions is, in round numbers, 6,000 volts per 3,000 volts of arrester rating. This is not the crest arrester voltage on the volt-ampere curve but a voltage on the descending part of the curve, near the so-called "cut-off". The initial voltage while carrying high current can be neglected because of its short duration. For purposes of calculation, then, it is assumed that 6,000 volts per 3,000 volts of arrester rating are applied continuously to the resistance and inductance of the

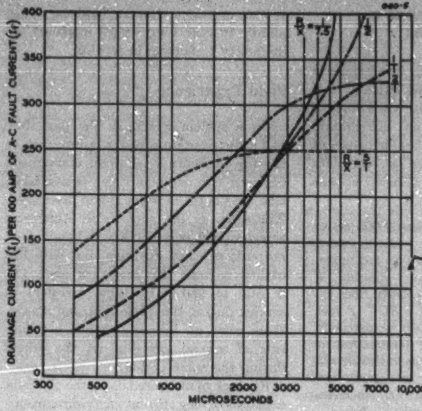


Figure 5. Surge current drained from arrester through line conductors and substation transformers

(Current I_1, in figure 4)

These curves based on $E_a=2.5E_n$ which is an arrester counter voltage of 6,000 on a 2,400-volt circuit or 18,000 on a 7,200-volt circuit

Since the range of a-c fault current (I_f) on a feeder is generally known, the drainage current I_1, which is proportional to it, was plotted accordingly. To use the curves, calculate I_f from R, X (60 cycles) and E_n of the figure 4 system, and use the appropriate R/X ratio curve in plotting the leakage current I_1 versus time

circuits through the supply and distribution transformers. These were found to have entirely different characteristics.

The substation transformer has connected to its receiving winding the supply system of low impedance. The current I_1 of figure 4 to the substation ground will build up through the inductance of the line, the leakage inductance of the transformer and the supply source, that is, in the ordinary a-c short-circuit path. In figure 5, I_1 is plotted per 100 amperes of feeder fault current for several values of the ratio R/X_{60}. These curves apply to higher voltage as well as 2,400-volts-to-neutral systems because the arrester counter voltage is proportional to the arrester rating. With small conductors, ($R/X=2/1$ to $5/1$, the drainage current to the substation ground is soon limited by line resistance.

The current I_2 flows in the other drainage path through the distribution transformers to ground. Since the secondary load impedances are high this current must build up through the magnetizing path. To determine the growth of current I_2, a $1^1/_2$-kva distribution transformer was subjected to suddenly applied continuous potential and the current measured by an oscillograph. Figure 6 shows the increase of current in terms of full load rms current of the transformers with 6,000 volts continuous applied to 2,400-volt windings or 18,000 volts applied to 7,200-volt windings. Until the iron begins to saturate at about 1,000 microseconds the current flow is imperceptible but after this it increases rapidly. The 1,000 microseconds applies under the conditions of test with no flux in the iron at the instant of application of the voltage. If the lightning voltage is applied at the instant the flux is zero, the curve applies as it stands. If the voltage appears when the flux is at its peak in the same direction, the time is much less, possibly zero. If it appears when the flux is at its opposite peak, the time will be much greater up to about twice 1,000 microseconds. To consider the most severe conditions it is assumed that 2,000 microseconds elapse before I_2 starts to flow.

The total current, I_1 plus I_2, that is drained away from arresters on typical 2,400- and 7,200-volt distribution systems is shown in figure 7. Up to 2,000 microseconds the drainage may be through the substation transformers only. Curves 1 and 2 show that for strokes near substations (3,000 to 1,000 kva, three phase) current is drained away rapidly. This also applies to a less extent on short heavy city feeders as shown in curve 3. Suburban and heavy rural circuits are represented in curves 4 and 5. Curve 6 applies to a typical rural circuit, while curve 7 represents extremely light rural distribution.

From curves 1, 2, and 3 of figure 7, it is apparent that for 1,000-ampere surges of long duration, the arrester discharge current will be reduced to zero in from 130 to 700 microseconds in city locations but for typical suburban distribution as indicated by curve 5, the arrester current will persist for some 2,500 microseconds where it is abruptly limited by drainage of current through the line transformers. The shape of curve 5 shows also that the suburban arresters are subjected to a higher average current.

On light rural systems the situation is the most unfavorable. The small size of the supply transformer and the high resistance of the line prevent much drainage to the substation. Fifteen miles of number 8 copper has a resistance of 53 ohms, which would pass only 340 amperes at the 18,000-volt counter voltage of a 9,000-volt arrester usual on a 7,200 volt system. Furthermore, the light branch fuses on these circuits are blown easily. With blown fuses, only the limited capacity of the distribution transformers can be depended upon for drainage, so conditions on grounded-neutral rural lines may be even worse than shown by curve 7.

In this connection it is suggested that the drainage of appreciable amounts of surge current through transformers may explain the occasional blowing of light transformer fuses with arresters connected on the line side of the fuses and no discernible evidence of flashover on the transformers.

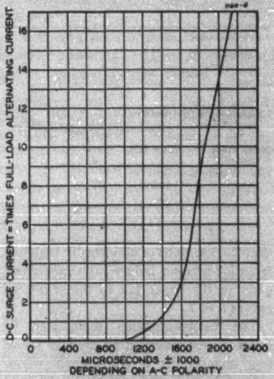

Figure 6. Surge current drained from arrester through magnetizing path of line transformers

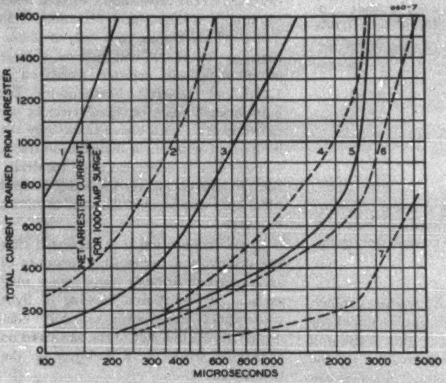
(Current I_2 in figure 4)

Based on applying direct voltage of 2.5 times rms alternating voltage rating of transformer, that is, $E_a=2.5E_n$ (figure 4) which is an arrester counter voltage of 6,000 on a 2,400-volt circuit or 18,000 on a 7,200-volt circuit. Load impedance is so high that secondary was considered open-circuited

While there are other factors already enumerated to be considered, experience has shown that the failure rate of arresters increases progressively with conditions represented by the ascending curve numbers of figure 7. We would also expect from this analysis that arrester failure rates on free-neutral systems should be higher than on grounded-neutral systems. It is further significant that the locations of abnormally high distribution-arrester failure rates mentioned early in the paper fall in the region of curves 5 to 7.



Below 2,000 microseconds, all current flows to the substation. (Current I_1 calculated from figure 5). Above 2,000 microseconds, the line transformers begin to saturate and I_2, calculated from figure 6, increases sharply. Actually, this may occur at any time from zero to 2,000 microseconds, depending on the instantaneous magnitude and polarity of the a-c magnetic flux in the iron at the time of the stroke. Refer to table below

Figure 7. Total current drained from arresters through transformers of typical distribution systems

	Curve Number:							
	1	2		3	4	5	6	7
Voltage to neutral	2,400	7,200 or	2,400	2,400	7,200	2,400	7,200	7,200
Substation transformer kva per phase	1,000	1,000 or	333	1,000	333	333	333	50
Size line conductor	None	None	None	No. 00	No. 4	No. 2	No. 4	No. 8
Miles from stroke to substation	0	0	0	2	5	5	20	15
Line transformer kva assumed all at one point	0	0	0	0	300	200	100	75

The fulchronograms reproduced in figure 3 were recorded on arrester phase legs installed at a transformer whose neutral is grounded. The circuit characteristics are such that for the assumptions made in figure 7, the current drained from the arresters should be in the region of curve 2. This curve predicts an arrester discharge duration of not much more than 300 microseconds. The fulchronograms of figure 3 appear to corroborate the calculations. Apparently, all of the evidence available to date supports the conclusions.

Application of Conclusions to Arrester Construction

The observations and investigations discussed in the foregoing explain to a large extent, at least, the variations in arrester failure rates on distribution systems as well as the probable causes of high failure rates. Thus far, the data presented are relative because not enough information on the actual wave shapes of discharge currents through arresters are at hand. Nevertheless, the conclusions appeared of sufficient importance two years ago to warrant an active investigation of arresters' ability to handle long discharges with the object of increasing this ability, without sacrifice of any of the high current capacity or protective characteristics. After all, the significance of the conclusions lies in whether they can be translated into a new and better arrester. Experience with an arrester tailored to these new concepts has been favorable. It gives additional corroboration and clarification to the aspects already discussed. The extremely low failure rate experienced with these arresters indicates that an increase in the ability to take long surges increases the immunity to failures in service.

Field Experience

On a system which, in the past, has had a distribution-arrester failure rate at the top of figure 2, a direct comparison between two arrester types is available. One type is the new one under discussion. The other is the superseded Autovalve arrester, with equal ability to handle high currents of short duration, but with less ability to take the long low ones. In a total of 950 of the new arresters in service during the 1939 lightning season, there were no failures, against a failure rate of several per cent on the others during the same period.

For lack of measured data, the ultimate demands in long current-carrying capacity are not yet known. Nor is it known exactly what can be done economically to meet what those ultimate demands may turn out to be, or to what degree the new arrester meets them. It will not eliminate failures entirely. However, on the basis of laboratory tests and field experience, it is expected that even in the unfavorable locations the failure rate will be low.

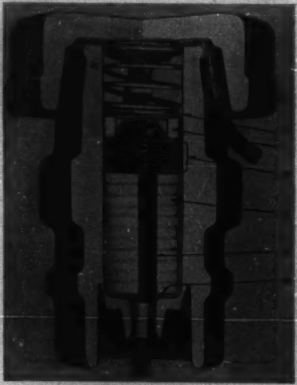


Figure 8. 3,000-volt Autovalve distribution lightning arrester, cutaway section

1—Porcelain-insulated main gap
2—Gap electrode with preionizing tips
3—Quenching gaps
4—Autovalve element with white insulating coating
5—Insulating coating cut away from element for purpose of illustration
6—Terminal plate, ground lead, and ferrule soldered together

The first field-trial installations were made in 1939, to gather operating experience before the design was adopted for production. Several thousand units were placed in locations where previous failure rates have been higher than normal. Two hundred fifty were in service throughout the 1938 season. No failures occurred. By the end of 1938 some 1,200 were installed. Before the spring of 1939, the number was 4,000, and this had more than doubled by the fall. There has been a total of four failures; one of these was definitely caused by system voltage. The other three occurred late last summer on the same system near the ends of lines. Inspection of these three arresters indicated that they were caused by lightning. Thus the lightning failure rate has been 0.043 per cent compared to the quarter of a per cent mentioned in the first paragraph of this paper.

Construction

The principal factor in determining the ability of the arrester to discharge long surges is the valve element. Its failure can be thermal, or it can be caused by a function involving current density, voltage gradient, and duration of discharge. In long-duration discharges the latter cause is more weighty than the thermal. The recognition of this was important for it pointed out a means of making a distribution arrester of large current-carrying capacity without increasing its cross section. If the length of the block is doubled and its composition adjusted so that the total voltage across it during discharge is the same as in the case of the shorter element, the voltage gradient is halved. This reduction in voltage gradient effects a large increase in the ability of the elements to handle discharges of long duration. The use of such an element in the arrester is the major reason for its large discharge ability. Other detail features permit the utilization of the valve material to its full capabilities; such as a newly developed insulating coating and a particular design of terminal for making contact with the valve blocks.

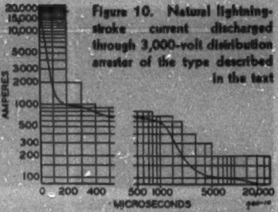

Figure 10. Natural lightning-stroke current discharged through 3,000-volt distribution arrester of the type described in the text

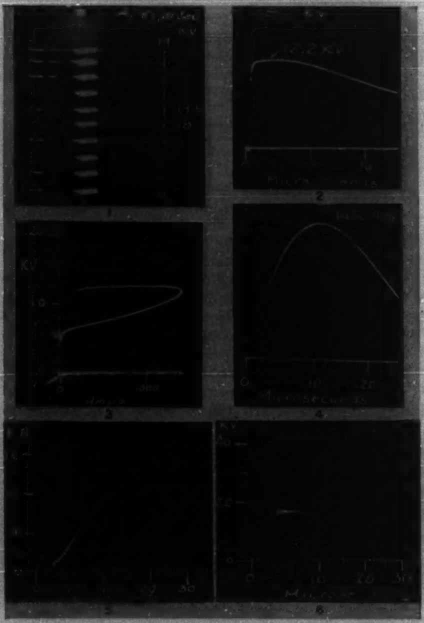
The current was derived from a lightning stroke to the Cathedral of Learning Building in Pittsburgh.[6] The current was recorded by a fulchronograph. After this test, the arrester was checked in the laboratory and found unchanged in its characteristics



1—Successive impulse breakdown tests on a 3,000-volt arrester. Rate of rise of test voltage 40 kv per microsecond. No time deflection used in oscillograph. Voltage deflection from left to right. Vertical line marked 19 is crest of 60-cycle breakdown

2—Volt-time curve of same arrester on AIEE test wave shown in 4

3—Volt - ampere characteristic of same arrester, test current as in 4

4—Ampere - time characteristic of test current used in 2 and 3

6—Volt-time characteristic of 3,000-volt arrester on test wave shown in 5

Figure 9. Impulse characteristics of new distribution arrester

The series gap structure consists of a quenching gap, item 3 in figure 8 with high 60-cycle interrupting ability, and a porcelain-insulated line or main gap, items 1 and 2. The high interrupting ability of the gap provides a margin of safety against failures from high system voltage. The use of mica spacers in the quenching gap and of a special main gap electrode, item 1, provides preionization of the gap spaces and produces low and consistent impulse breakdowns, as illustrated in oscillogram 1 of figure 9, which also shows the discharge characteristics of the arrester on the basis of AIEE standards. The favorable impulse ratios obtained with this construction permit the incorporation of a high 60-cycle breakdown, thereby providing additional margins against dynamic voltage failures.

During the development of this arrester, many tests were made with moderate discharge currents of long duration as well as with high currents. A novel test was completed when a lightning stroke occurred to a measuring station on the roof of Pittsburgh University's Cathedral of Learning.[6] The entire stroke current was discharged through one of the new distribution arresters, connected in the stroke-current circuit, and was recorded by a fulchronograph. This current is shown in figure 10. Subsequent laboratory tests on the arrester showed that its condition had not been altered by the discharge. As far as the authors are aware, this is the first time that an arrester has deliberately been put in the path of a stroke and successfully discharged the full stroke current. The performance of the arrester on laboratory surges of long duration and of high magnitude are shown in figures 11 and 12. Oscillogram 1 of figure 11 is typical in shape of the surge used in routine testing of valve elements to insure the use in complete arresters of only

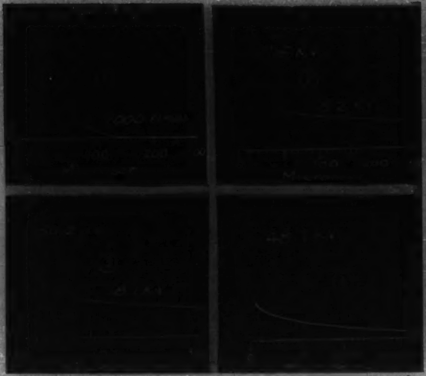

Figure 11. Performance of distribution arrester on long surge

1—Discharge current through arresters used in recording 2, 3, and 4

2—Volt-time characteristic of 3,000-volt arrester with discharge current of 1

3—Volt-time characteristic of 9,000-volt arrester with discharge current of 1

The points on 2 and 3 marked 6.2 and 18.1 kv are the voltages corresponding to 1,000 amperes in 1. These are the basis for assuming 6,000 volts per 3,000 volts of arrester rating in the derivation of figures 5, 6, and 7

4—Volt-time characteristic of 9,000-volt arrester with long time scale. This oscillogram shows that there is voltage across the arrester even after 4,000 microseconds, indicating that the arrester is still discharging current. In 1, the current is not discernible after 150 microseconds because of the current scale used

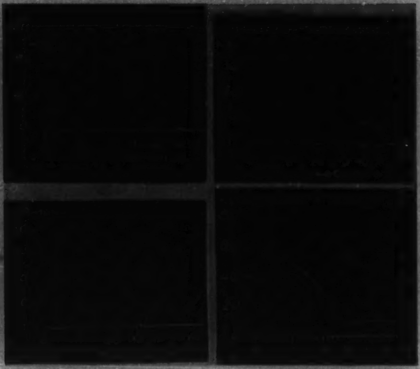

Figure 12. Performance of distribution arrester on high discharge currents

1—High current discharge through 3,000-volt arrester

2—Volt-time characteristic of 3,000-volt arrester with discharge current of 1

3—High current discharged through 9,000-volt arrester

4—Volt-time characteristic of 9,000-volt arrester with discharge current of 3

The difference in current between the 3,000- and 9,000-volt arresters is caused by the difference in the counter voltage of the two. Both were tested in the same surge-generator circuit. The voltage across the 9,000-volt arrester for the current in 1 is three times the voltage recorded in 2

elements able to handle long-tailed discharges.

This test surge used on distribution arrester elements resembles the recorded discharge currents of figure 3, but is longer in duration. The routine test is made while the arresters are excited at rated 60-cycle voltage. The adoption of such a test procedure is perhaps as important a development as the new construction used in the arrester.

Other characteristics have been given due weight in the development, such as safeguards against lockouts by failed arrester on low-capacity systems, and the avoiding of interference with radio reception. Discussion of these is without the scope of this paper. However, the authors wish to say a few words on the matter of radio interference.

Radio interference has not been a problem in arresters constructed during the past eight years. Laboratory tests with standardized radio-noise-measuring technique are factors in the development of any arrester. However, a considerable amount of attention is being directed to this subject as well as to so-called ionization currents, synonymous with radio-noise currents. For this reason it is to be desired that the committees concerned with this question adopt standards of permissible microvolt levels to which the industry will subscribe and adhere. In this connection, it may be of interest that in the arrester discussed in this paper the occurrence of low ionization currents at a voltage below actual arrester breakdown but above its rating is promoted and utilized to achieve low and consistent impulse breakdown.

Summary

The text of this paper concerns itself almost entirely with one aspect of the problem of distribution circuit protection, that of arrester discharge currents and the lightning-arrester failure rate. There are other phases of the problem such as the important one of protection to equipment. At this time, however, it is believed that the most important problem is the matter of eliminating as far as possible the failures of protective devices even under severe operating conditions. It is hoped that the work described in the paper has contributed to the solution of this problem, and there is some reassuring evidence that it has, contained for instance in the field records of an arrester designed to meet conditions disclosed by the studies already outlined.

Table I. Summary of Arrester Characteristics

Arrester rating, volts	3,000	6,000	9,000
60-cycle breakdown, volts rms	14,000	24,000	35,000

Much research has been done on lightning, particularly on the lightning stroke. This will no doubt result, in time to come, in important new concepts of protection. However, the present practical aspect of the protective problem is concerned with the discharges through lightning protective devices in service, and not with the currents in direct strokes. For this reason, the authors attach the greatest importance to an accumulation without delay of a volume of statistical data on the magnitude and wave shape of such discharge currents, to permit a definite evaluation of the present means of protection, the economic possibilities,

Watt-Hour-Meter Performance With Power Rectifiers

Synopsis: This paper gives the results of tests made principally to determine the effect of 6- and 12-phase mercury-arc power-rectifier loads on the performance of typical polyphase watt-hour meters. Schematic diagrams of the connections used and oscillograms of the rectifier voltage and current waves are included. The results indicate that the effect to be expected will be well within one per cent.

IT IS well known that mercury-arc power rectifiers introduce harmonics in the alternating supply current and voltage waves [1-4] and this has been thought to affect adversely the accuracy of watt-hour meters on circuits including rectifiers. The subject has been investigated previously, notably by Dannatt,[5] but interest in it is still current. It was considered highly desirable, therefore, to make more comprehensive tests, utilizing the best obtainable equipment and methods, to determine the actual effect of commercial types of 6- and 12-phase rectifiers under approximate conditions of service on the performance of typical polyphase watt-hour meters used with instrument transformers. At the suggestion of W. C. Wagner, a var-hour meter (reactive-volt-ampere or rva-hour meter) was included; also included was a portable power-factor meter.

In these tests, the performance of five watt-hour meters was determined at various loads, first with one of the two rectifiers and second with a sine-wave supply under corresponding three-phase conditions. The differences between the meter accuracies thus obtained are a measure of the effect of the rectifier and are referred to the sine-wave results as a standard. A similar procedure was followed for the var-hour and power-factor meters.

The paper first summarizes the test results, then describes briefly the apparatus tested and the related theories of performance, outlines the procedure followed, and discusses the data obtained. The ratings of the apparatus are given in table I and part of it is shown in figures 1 and 2. Schematic diagrams of the test connections are shown in figures 3 and 4 and the measurement equipment in figure 5.

Summary of Results

The results of the watt-hour meter tests are given in table II, which shows that the maximum change in watt-hour meter performance due to the effect of the rectifiers is less than 0.5 per cent. Table II gives the detailed effects or the differences between the accuracies obtained with the rectifiers and with a sine-wave supply at corresponding points for the five watt-hour meters tested. The accuracies so obtained in the 6-phase rectifier tests are included in table III and are plotted in figure 8; the 12-phase rectifier results are plotted in figure 9. In general, the results obtained with the two rectifiers and the two types of meters are similar in magnitude. In both tests, the rectifier effect tends to decrease the meter speed at light load. At higher rectifier outputs, the 6-phase effect tends to increase the meter speed, whereas the 12-phase effect becomes negligible.

Three representative oscillograms taken during the 6-phase rectifier tests are shown in figure 6 and the analyses are given in table IV, part 1. This table includes an analysis of the oscillogram shown in figure 7 for a 12-phase rectifier. The maximum harmonics occur with the 6-phase rectifier, but the harmonic power is small, as indicated in table V.

The results of the var-hour meter tests are given in table III and are plotted in figure 10. The maximum change shown in var-hour meter performance due to the 6-phase rectifier is less than one per cent. The rectifier effect tends to increase the meter speed at light load and to decrease it at higher outputs.

Table III also gives the results of the power-factor meter tests, together with the instrument readings from the watt-hour meter tests. Three values of power

Discussion

Discussion will be found in the 1940 annual Transactions volume and in the 1940 "Transactions Supplement" to Electrical Engineering.

factor are given for each pair of tests as follows:

(*a*). Power-factor-meter reading

(*b*). Power factor calculated from the formula

$$\text{power factor} = \text{polyphase watts/voltamperes} = P/\sqrt{3}EI \quad (1)$$

(*c*). Vector power factor calculated from the formula

$$\text{vector power factor} = \text{polyphase watts} \div \sqrt{\text{watts}^2+\text{vars}^2} = P/\sqrt{P^2+Q^2} \quad (2)$$

Formulas 1 and 2 are based on American Standards Association definitions; they are here restricted to balanced circuits, as is (*a*).

With the sine-wave supply, the power-factor-meter readings (*a*) in table III agree fairly well with the two corresponding calculated values of power factor (*b*) and (*c*) in each case. With the 6-phase rectifier, the expected good agreement is shown between the power-factor-meter readings (*a*) and the corresponding calculated values of vector power factor (*c*). Good agreement is not expected between the power-factor-meter readings (*a*) and the corresponding calculated values of power factor (*b*) based upon the ASA definition; the maximum difference shown is 0.030 (=0.976–0.946) or about three per cent: this difference is a function of the harmonics present.

The rectifier effect represented by the difference between (*a*) and (*b*) may be expressed by the ratio (*a*)/(*b*), which here has a maximum value of 1.032 (=0.976/0.946), or as (*c*)/(*b*). The lowest power-factor values are those determined from equation 1.

Conclusions

The rectifier current and voltage waves obtained in the tests are believed to be fairly representative of those encountered in practice.

The maximum effect of such rectifier waves on the performance of watt-hour meters should be well within one per cent; this conclusion is based upon all of our experience to date. The corresponding limit for a var-hour meter should be two per cent.

The effect of a 12-phase rectifier on the power factor should be less than the three per cent (ratio 1.032) obtained with the 6-phase rectifier. For both 6- and 12-phase rectifiers, the ratio (*a*)/(*b*) should aproximate the ratio

$$\frac{\text{effective value of balanced line currents}}{\text{effective value of fundamental component}} \quad (3)$$

when the harmonics in the balanced voltage waves are small as in these tests. The maximum value obtainable for ratio (3) with a 6-phase rectifier is 1.045 and it is 1.010 with a 12-phase rectifier. Thus, the maximum differences to be expected between the readings of a power-factor meter and the power factor calculated from equation 1 with such rectifiers should be within five per cent and two per cent, respectively.

The significance of the terms "power factor" and "reactive power" when harmonics exist in the system current and voltage waves is a matter of opinion[5–8].

The results upon which table II is based are believed to be correct within ±0.2 per cent.

Mercury-Arc Power Rectifiers

A 6-phase rectifier tank is shown in figure 1. The auxiliary equipment includes a main power-supply transformer in one or three units connected to convert 3-phase power to 6- or 12-phase power, an interphase transformer, vacuum pumps, and suitable control devices.[3,4]

The function of a complete rectifier is to convert a-c power to d-c power, usually for electric traction or electrochemical purposes. In so doing, it draws nonsinusoidal currents from a system generating sinusoidal voltages. These currents, in flowing through the system impedances, create nonsinusoidal voltage drops, which combine with the line voltages to give nonsinusoidal voltages at the rectifier terminals. The nonsinusoidal currents are composed of the fundamental and various harmonics, the orders of which depend on the number of rectifier phases; the magnitudes are an inverse function of the orders.[1] The nonsinusoidal voltage drops have the same harmonics, but the harmonic magnitudes depend on the magnitudes of the system impedances as well as on the magnitudes of the currents.[2] The formulas for the order and magnitude of the harmonic currents are as follows:

$$\text{Order of harmonic } n = mp' \pm 1 \quad (4)$$

$$\text{Per cent harmonic } h = 100/(mp' \pm 1) = 100/n \quad (5)$$

where

m = any number from 1 to infinity
p' = number of rectifier transformer secondary phases

The maximum obtainable percentage values of the harmonic currents due to the rectifier occur at light load and these estimated values are shown for 6- and 12-phase rectifiers in table IV, part 2*A*, up to the 25th harmonic, the fundamental being taken as 100 per cent; the orders of the harmonics also are shown. It should be noted that the magnitude of the harmonics decreases as their order increases and that harmonics common to both rectifiers, such as the 11th and 13th, have identical respective values. In practice, these magnitudes will ordinarily be somewhat less than those listed. Also, due to various causes, small amounts of the 5th, 7th, 17th, and 19th harmonics will be present with 12-phase rectifiers. For a given rectifier, the percentage harmonics will decrease with load, but the actual harmonic currents will increase; in other words, the harmonic components do not increase as fast as the fundamental.

Different rectifiers may be compared as to the relative amounts of harmonics expected in the input currents at full load by means of the load coefficient. The formula is:

$$\text{Rectifier load coefficient} = IX/E_s \quad (6)$$

where

I = d-c load current per group of main-transformer secondary windings

X = reactance of circuit in which commutation takes place

E_0 = crest voltage to neutral of main-transformer secondary winding

The effect of IX/E_0 at full load in reducing the light-load harmonic percentages is shown in table IV, part 2B for assumed values of 0.04 and 0.08: the latter is considered representative of many rectifiers. For example, take the 13th harmonic. For both rectifiers, "39" corresponds to 0.08, which means that 39 per cent of the light-load harmonic of 7.7 per cent will be present; this gives 3 per cent for the 13th harmonic: the corresponding value for $IX/E_0 = 0.04$ is 5 per cent. The percentage of harmonic present tends to decrease as the order of harmonic increases; the decrease for the 5th harmonic is small: conversely, the percentage increases with decreasing values of IX/E_0.

The term X in IX/E_0 represents the sum of the system reactance and that of the rectifier transformer; the system reactance (and the losses therein) ordinarily is less than ten per cent of the total. The harmonic power to be measured, therefore, is but a small part of that due to the rectifier, which in turn is but a small part of the fundamental power. The harmonic and fundamental powers have opposite signs. If the system voltage itself contains some of the harmonics expected from the rectifier, however, the net harmonic power may be positive instead of negative.

Ratio (3) is a function of the harmonics in the input currents. The maximum value of 1.045 for this ratio with a 6-phase rectifier is obtained when all possible harmonics attain the maximum possible magnitude; table IV, part 2, includes those up to the 25th. The maximum value of 1.01 is similarly obtained with a 12-phase rectifier.

Watt-Hour Meters

One of the type *DS*-19 watt-hour meters tested is shown in figure 2*A* and one of the type *V*-3-*A* meters in figure 2*B*. Both types have the same rating and are designed for three-phase three-wire service, usually with instrument transformers. The switchboard-type *DS*-19 meter employs two electromagnetic structures and two disks mounted on a common

shaft. The bottom-connected type *V*-3-*A* meter employs a more recent construction, in which both electromagnets act on a common disk. Interference is rendered negligible by the use of magnetic shields and by laminating the disk, thereby segregating the fluxes and eddy currents.

Tests made here and elsewhere have shown that such induction-type meters tend to become slower as the applied frequency increases. Thus 60-cycle meters would be slow at 300 cycles; in other words, they would not register fifth harmonic power correctly and larger errors would be obtained with higher harmonic powers. In some cases, correlation has been shown[5,10,11] between the performance of a meter on distorted waves and its performance on the component harmonic frequencies.

Var-Hour Meter

The var(rva)-hour meter tested is a type *DS*-19 watt-hour meter with its two potential circuits supplied from a type *MC*-1 double autotransformer instead of directly from the two line-to-line system voltages. By means of suitable taps, the autotransformer lags each voltage 90 degrees in order to measure the reactive component of the energy.[9] A similar unit supplied two indicating watt(var) meters to measure the reactive power.

The active power in a balanced three-phase three-wire sine-wave circuit may be determined from the formula

$$\text{watts} = \text{line-to-line volts} \times \text{line amperes} \times \sqrt{3} \times \cos\theta = \sqrt{3}EI \cos\theta \qquad (7)$$

where θ is the angle between the voltage to neutral and the line current. Similarly, the reactive power may be obtained from the formula

$$\text{vars} = \sqrt{3}EI \sin\theta \qquad (8)$$

The former quantity may be measured by two wattmeters and the latter by two varmeters. The varmeters will function correctly also on circuits with unbalanced currents, but neither formula can be used as the line currents are unequal and θ is meaningless. The wattmeters will function correctly on any sort of three-wire circuit.

Equations 7 and 8 may be used for balanced circuits and "θ" may be taken to represent the "angle" between voltage and current when the current waves contain harmonics. However, each wattmeter then measures the product of its sine-wave voltage and the in-phase component of its current. Since the fundamental component is smaller than the total current, the correct power factor (by ASA definition) or cos "θ" obtained from equation 1 will be smaller and "θ" will be larger than if no harmonics were present. Therefore, sin "θ" and the calculated reactive power will be larger than the measured value, the difference

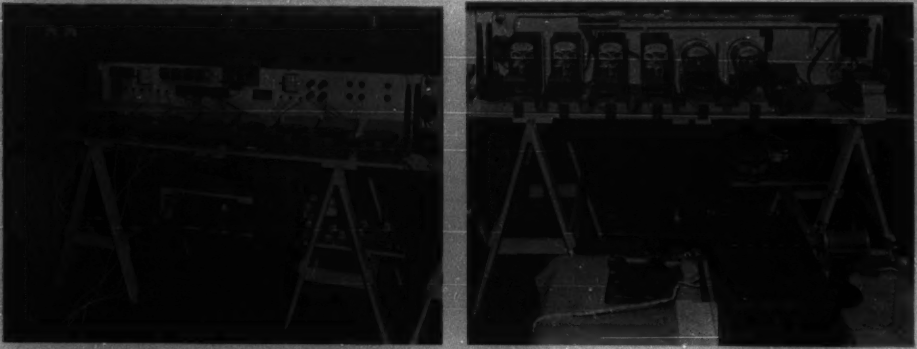

Figure 5. Measurement equipment—indicating instruments and transfer panel, sine-wave loading devices and control—watt-hour meters, revolution counters, chronograph and oscillograph

being a function of ratio (3). Also the vector power factor or cos θ determined from equation 2 will be the same as that read on a power-factor meter and both will be greater than the value determined from equation 1 in the ratio (3).

The foregoing discussion will still be pertinent when the harmonics in the voltage waves are small. However, it has been shown[8] that correct measurement of reactive power is impossible when the harmonics in both the voltage and current waves are appreciable.

Power-Factor Meter

The type *P*-3 portable power-factor meter tested is designed for use on balanced three-phase three-wire circuits only and has one current coil, which is connected in series with the "common" line. There are two potential coils mounted at an angle on the shaft and the two potential circuits are connected from the other two lines to the "common" line. Essentially, two wattmeters are combined in one instrument without a control spring, so the deflection depends on the ratio of the two torques, which is a function of the power-factor angle θ. The scale is marked in power factor and the range is from 0.5 lag through 1.0 to 0.5 lead.

Test Connections and Procedure

The tests described herein were made in connection with the standard acceptance tests on the two rectifiers. The measurement equipment is shown in figure 5. The meter accuracies were determined first with one of the two rectifiers and second with the sine-wave supply. The correct three-phase watt (or var) values were obtained in each test from the readings of two single-phase watt (or var) meters, which were checked with the d-c supply by means of potentiometers. The correct power factor was calculated from equation 1, which requires the readings of eight different instruments.

CONNECTIONS

The connections used are shown schematically in figures 3 and 4. Figure 3*A* shows the general arrangement of the rectifier input and output circuits and indicates the feed-back scheme adopted for acceptance tests on large rectifiers. The small numbers on the instrument transformer secondary leads correspond to similar numbers in figure 3*B*, which shows the arrangement for the watt-hour meter tests. The arrangement for the

var-hour and power-factor meter tests is shown in figure 3*C*. In *B* and *C*, meters not under test are indicated by dotted lines. Figure 3*D* indicates the arrangement for the sine-wave supply, which constituted the standard test condition for all meters.

The necessary connection changes were made by means of single- and double-throw potential switches, type *PK*-2 potential and current test blocks, and potential and current receptacles and plugs. These are shown in figure 4*A*. In the rectifier tests, the magnitude of the currents through the various instruments and the six meters (not shown) was determined by the load on the rectifier. In the sine-wave checks, the corresponding currents and power factors were obtained by means of the variable noninductive and inductive loads shown at the bottom of figure 4*A*. The line-to-line voltages were set at approximately the desired values by means of remote generator field control.

The method of automatically counting the revolutions of the six meter disks is shown in figure 4*B*. A small mirror is fixed on each meter shaft to reflect the light from a small lamp to photoelectric tube 922. This tube operates the coil of a suitable pen through a tube network. Each pen records each revolution of its meter on the moving chronograph chart, which also is marked by two pens (one at each side of the chart) energized every second from a standard clock.

PROCEDURE

For a test run on the watt-hour meters with the rectifier supply, the chronograph chart was started and allowed to record the meter revolutions for a period of eight minutes, during which the two indicating wattmeters were read every ten seconds, making a total of 48 readings each. Readings were taken every 30 seconds on each voltmeter and ammeter, giving a total of 16 readings per instrument. Thus one observer was required for each wattmeter, one for the three voltmeters, and one for the three ammeters, making a total of four.

Next a test run was taken on the var-hour and power-factor meters and the chronograph chart was permitted to record the meter revolutions for five minutes, during which a total of 30 readings were taken on each of the two varmeters and on the power-factor meter and ten readings were taken on each voltmeter and ammeter. An extra observer was required for the power-factor meter.

The watt- and var-hour meter tests just described were checked by corresponding tests with the sine-wave supply, the secondary voltage, current, and power-factor values due to the rectifier load in each case being duplicated as closely as possible. The actual running time for the four tests at each load was 26 minutes.

Finally, the indicating watt (or var) meter readings taken in the a-c tests were checked with the d-c supply. Reversed readings were taken at each point, using two deflection potentiometers, one for voltage and the other for current, as standards.

After completing the tests, the readings of each indicating instrument were av-

* The load coefficient has a negligible effect on the magnitude of the harmonics at light load.

** Based on an inductive load; for a noninductive load, the fifth harmonic value is higher (= 22.6) but the other harmonic values are lower (or unchanged), so the maximum possible composite value is practically unchanged.

† Test made on 3,000-kw rectifier.

eraged and corrected for scale error. To obtain the three-phase volt-amperes, the three corrected voltmeter readings in each test were averaged, as were the three ammeter readings and these average values E and I were used in the formula.

$$\text{three-phase volt-amperes} = \sqrt{3}EI \qquad (9)$$

In each watt-hour meter test, the polyphase watts were obtained by adding the corrected readings of the two wattmeters and these indicated watts constituted the standard of reference in determining the meter accuracies. The recorded meter watts were determined from the total revolutions recorded on the chronograph chart and the corresponding elapsed time. The accuracy formula is

$$\text{per cent accuracy} = \text{recorded watts/indicated watts} \times 100 \qquad (10)$$

A similar procedure was followed for the var(rva)hour meter, the formula being

$$\text{per cent accuracy} = \text{recorded vars/indicated vars} \times 100 \qquad (11)$$

In these tests, however, the polyphase vars were obtained from the difference between the two varmeter readings. The reactive factor (sin "θ") was determined from the formula

$$\text{reactive factor} = \text{polyphase vars/volt-amperes} = Q/\sqrt{3}EI \qquad (12)$$

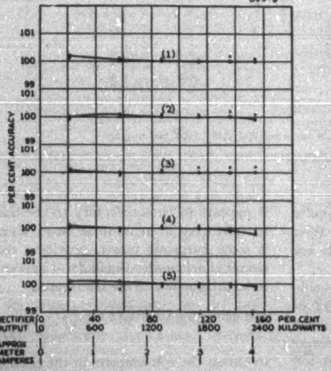

Figure 8 (left). Watt-hour-meter accuracies with six-phase rectifier and with sine-wave supply

Figure 9 (right). Watt-hour-meter accuracies with 12-phase rectifier and with sine-wave supply

Curves 1, 2, 3—Type *DS*-19 meters

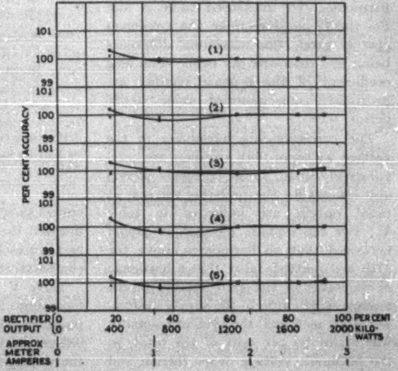
Circles—Sine-wavesupply

Crosses—With rectifier load



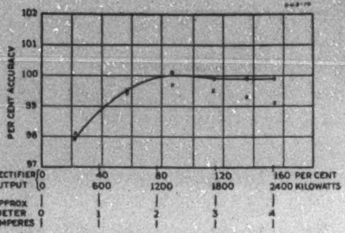


Figure 10. Accuracy of type DS-19 var (rva)-hour meter with six-phase rectifier and with sine-wave supply

Circles—Sine-wave supply
Crosses—Six-phase rectifier

Power factor (cos θ) was read directly on the power-factor-meter scale and for comparison was calculated from equation 2.

No corrections for the watts or vars were necessary because of the instrument transformers in the rectifier tests, since the meters were compared directly with the instruments in the secondary circuits.

Discussion of Results

Wave Shapes

A comparison of the current wave shapes in figure 6*A* at light load on the 6-phase rectifier with the theoretical waves, as shown by the magnitudes of the several harmonics in table IV, parts 1 and 2, indicates that the test harmonics are less than the theoretical ones by a maximum of about four per cent.

A much better agreement is found between the current wave shapes in figure 6*B* at rated output on the 6-phase rectifier and the theoretical waves based upon table IV, part 2*B*. The calculated harmonics check the test harmonics closely, the maximum difference being about two per cent for the seventh harmonic: the measured value is low. For the 12-phase rectifier, the agreement also is good, the maximum difference being less than one per cent. The load coefficient of the 6-phase rectifier approximates one assumed value (0.086 versus 0.08).

The corresponding harmonics in the voltage waves of both rectifiers are comparatively small, so the harmonic powers also are small; the probable maxima at rated output are indicated in table V. For the 6-phase rectifier, it should be noted that all harmonics above the 17th are omitted; also, that a harmonic in the order of the 49th appears in the voltage waves, due to the supply system. For both rectifiers, the system reactance was about 20 per cent of the total, so the harmonic voltage drops therein and the resulting harmonic powers are somewhat greater than would ordinarily be expected in service.

Meter Performance

The watt-hour-meter per-cent accuracies listed in table III have been corrected for minor errors in meter adjustment. For example, the actual test per-cent accuracies obtained for meter number 5 at 2.5 amperes in the sine-wave checks for both rectifiers were the same: 100.32, so 0.32 was subtracted from all test values. This procedure is equivalent to adjusting each meter to register correctly at its rated current of 2.5 amperes, in so far as comparative values are concerned. As just indicated, all results were carried out to the nearest 0.01 per cent and then rounded off to the nearest 0.1 per cent. The accuracy curves shown in figures 8 and 9 are quite flat and the differences between rectifier and corresponding sine-wave points are comparatively small.

Table V indicates that the probable maximum harmonic power for the 6-phase rectifier at rated output is about 0.6 per cent of the fundamental power; the corresponding values at 22 and 156 per cent output are 0.7 and 0.9 per cent, respectively. These apparent differences are not sufficient to account for the differences in effect on the meter speed. Although the phase relations of the several components of the harmonic power and therefore the true harmonic power itself at any output were not determined, there is no reason to expect that the net harmonic power changes sign as the rectifier output increases. In other words, there appears to be no correlation between the harmonic power and the rectifier effect. The probable maximum is less than 0.2 per cent for the 12-phase rectifier. It seems logical to conclude first, that the harmonic power due to 6- and 12-phase rectifiers will be comparatively small in practice and second, that their effect on the accuracy of modern watt-hour meters will be negligible.

Var-Hour and Power-Factor Meters

The var-hour-meter results are given in table III. The accuracy curve shown in figure 10 is fairly flat at the higher rectifier outputs, but it turns down toward light load; the differences between rectifier and sine-wave points are, in general, greater than for the watt-hour meters.

Table III also gives the power-factor-meter readings (*a*) and these agree fairly well with the corresponding values (*c*) calculated from equation 2. In fact it appears to be satisfactory to use this formula even if, as in these cases, there is some harmonic power, providing the circuit is balanced. Similarly, it appears to be satisfactory to use the formula

$$\text{volt-amperes} = \sqrt{\text{watts}^2 + \text{vars}^2} = \sqrt{P^2 + Q^2} \quad (13)$$

to obtain the volt-amperes in the circuit,

* Harmonic values taken from table IV (1), 6-phase rectifier values from test number 4.

** Relative harmonic volt-amperes at an assumed power factor of unity equals relative harmonic power in watts.

when not otherwise available. The ratio measured/calculated volt-amperes as obtained from equations 9 and 13, respectively, should approximate ratio (3) whenever the harmonics in the balanced voltage waves are small. This also applies to the ratio of power factors calculated from equations 2 and 1.

The average value of ratio (3) in 6-phase rectifier test numbers 1, 4, and 6*a* is 1.021 (from table IV, part 1). This compares with 1.025, which represents the average ratio for the same three tests between the two calculated power factors (table III, (*c*) and (*b*)). It appears that the voltage harmonics do not exert an appreciable effect.

It has been emphasized that the type *P*-3 power-factor meter is for use on balanced circuits only. In these tests, the circuit balance cannot be determined from the tables, as the averages of the voltages and currents instead of the individual values are given to conserve space. In general, excellent balance was obtained in the six-phase rectifier tests and in the corresponding sine-wave check tests, the maximum difference between any of the three voltages or between any of the three currents being in the order of one per cent.

Discussion

Discussion will be found in the 1940 annual TRANSACTIONS volume and in the 1940 "Transactions Supplement" to ELECTRICAL ENGINEERING.

Transient Analysis of Symmetrical Networks by the Method of Symmetrical Components

LOUIS A. PIPES
ASSOCIATE AIEE

Synopsis: The canonical equations of a general, linear, bilateral symmetrical network of *n* meshes on which are impressed arbitrary mesh voltages are subjected to a Laplacian transformation. The transformed equations are then subjected to a symmetrical component transformation. By the use of these transformations the transient behavior of an *n* mesh symmetrical network subject to impressed arbitrary voltages and initial currents and charges is readily obtained. The solution of the usual determinantal equation is avoided.

SINCE the introduction of the method of symmetrical components into electrical engineering by Fortescue in his classic paper,[1] there have been many extensions and expositions of the method.[2,3] It appears however, that no systematic exposition of the use of symmetrical components in the study of transients in linear, constant, bilateral symmetrical networks has appeared. It is the purpose of this discussion to present such an exposition. The methods of the Laplacian transformation and matrix algebra as presented in references 4 and 5 respectively will be assumed.

I. The Canonical Equations

Let us consider a general, linear, constant, bilateral, lumped *n*-mesh network. Let the *n* mesh currents have the instantaneous values $(i_1 \ldots i_n)$ and let there be *n* voltages $(e_1 \ldots e_n)$ acting on the contours of the *n* meshes. The canonical equations of such a general *n*-mesh circuit may be written in the form:

$$(e) = [Z](i) \tag{1}$$

Where (*e*) and (*i*) are columnar matrices whose elements are the *n* mesh voltages and currents respectively and $[Z]$ is a square matrix of the *n*th order whose elements are the various self and mutual impedance operators of the form:

$$Z_{rs} = L_{rs}d/dt + R_{rs} + S_{rs}\int_{-\infty}^{t} (\;)dt \tag{2}$$

and L_{rs}, R_{rs}, S_{rs} are the coefficients of self- and mutual inductance, resistance, and elastance of the system. The impedance operator matrix $[Z]$ has the important property of being symmetrical about the principal diagonal. This property follows from the relations:

$$L_{rs} = L_{sr} \tag{3}$$

$$R_{rs} = R_{sr} \tag{4}$$

$$S_{rs} = S_{sr} \tag{5}$$

II. E-Symmetric Systems

Many networks of practical importance have the property that their impedance operators satisfy the relations:

$$Z_{11} = Z_{22} = \ldots. = Z_{nn} = Z_0 \tag{6}$$

$$Z_{sr} = Z_{jk} = Z \text{ for } r \neq s,\ j \neq k \tag{7}$$

that is, the impedance matrix of these systems has the form:

$$[Z] = \begin{Vmatrix} Z_0 & Z & Z & Z \ldots Z \\ Z & Z_0 & Z & Z \ldots Z \\ \ldots & \ldots & \ldots & \ldots \\ Z & Z & Z & Z \ldots Z_0 \end{Vmatrix} \tag{8}$$

Such networks have equal self-impedance operators among the several meshes and also equal mutual impedance operators between the meshes. Networks exhibiting this type of symmetry are called *E*-symmetric and are of great technical importance. Symmetrical polyphase systems are of this type.

III. The Laplacian Transformation of the Canonical Equations

Following the method of (5) part II, we subject the canonical matrix equation

---

Paper 40-2, recommended by the AIEE committee on basic sciences, and presented at the AIEE winter convention, New York, N. Y., January 22–27, 1940. Manuscript submitted August 8, 1939; made available for preprinting November 3, 1939; released for final publication March 13, 1940.

LOUIS A. PIPES is faculty instructor in electrical engineering, Harvard University, Cambridge, Mass.

1. For all numbered references, see list at end of paper.

(1) to a Laplacian transformation as follows:

Let

$$I_j(p) \div i_j(t) \qquad (I) \div (i) \tag{9}$$

$$E_j(p) : e_j(t) \qquad (E) \div (e) \tag{10}$$

that is, for each element of the current matrix (I) and the voltage matrix (E) of (1) we introduce its Laplacian transform. Then the matrix equation (1) is transformed into:

$$[Z(p)](I) = (E) + p[L](i^0) - [S](q^0) \tag{11}$$

where:

$$(i^0) = \begin{Vmatrix} i_1^0 \\ i_2^0 \\ \cdots \\ i_n^0 \end{Vmatrix} \tag{12}$$

and ($i_1^0 \ldots i_n^0$) are the initial mesh currents at $t=0$ in the system,

$$(q^0) = \begin{Vmatrix} q_1^0 \\ q_2^0 \\ \cdots \\ q_n^0 \end{Vmatrix} \tag{13}$$

($q_1^0 \ldots q_n^0$) represent the n initial mesh charges at $t = 0$.

$$Z_{mn}(p) = L_{mn}p + R_{mn} + S_{mn}/p \tag{14}$$

$$[L] = [L_{mn}] \text{ the inductance matrix} \tag{15}$$

$$[S] = [S_{mn}] \text{ the elastance matrix} \tag{16}$$

IV. Transformation to Symmetrical Components

In the theory of symmetrical components,[1] the transformations are effected by the use of the nonsingular, symmetric matrix:

$$[C] = [C_{rs}] \tag{17}$$

where

$r = 1, 2, \ldots n$
$s = 1, 2, \ldots n$

$$C_{rs} = a^{-(r-1)(s-1)} \tag{18}$$

$$a = \epsilon^{j2\pi/n} \tag{19}$$

The transformation matrix $[C]$, is thus a square matrix of the nth order with the important properties that:

$$[C]' = [C] \tag{20}$$

where $[C]'$ is the transpose matrix of $[C]$

$$[C]^{-1} = \frac{1}{n}[\text{conj } C] \tag{21}$$

where $[C]^{-1}$ is the inverse of $[C]$ and $[\text{conj } C]$ is the conjugate of $[C]$. The rows of $[C]$ are the sequence operators of Fortescue.

Let us now multiply both sides of the equation (11) on the right by $[C]^{-1}$. We then obtain:

$$[C]^{-1}[Z][C][C]^{-1}(I) = [C]^{-1}(E) + p[C]^{-1}[L][C][C]^{-1}(i^0) - [C]^{-1}[S][C][C]^{-1}(q^0) \tag{22}$$

Now let us introduce the notation:

$$(E)_s = [C]^{-1}(E) \tag{23}$$

$$(I)_s = [C]^{-1}(I) \tag{24}$$

$$[Z]_s = [C]^{-1}[Z][C] \tag{25}$$

$$[L]_s = [C]^{-1}[L][C] \tag{26}$$

$$[S]_s = [C]^{-1}[S][C] \tag{27}$$

Then equation 22 may be written in the form:

$$[Z]_s(I)_s = (E)_s + p[L]_s(i^0)_s - [S]_s(q^0)_s \tag{28}$$

V. Transformation of the E-Symmetric System

Let us consider the transforms of the equations of the E-symmetric system of part II. In this case, the impedance matrix has the form given by (8). Computation of the symmetrical component matrix of the E-symmetric system by the equation (25) gives:

$$[Z]_s = \begin{Vmatrix} [Z_0+(n-1)Z] & 0 & 0\ldots & 0 \\ 0 & (Z_0-Z) & 0\ldots & 0 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0\ldots & (Z_0-Z) \end{Vmatrix} \tag{29}$$

that is, the symmetrical component transformation matrix $[C]$, transforms the impedance matrix of the E-symmetric network into the diagonal form (29).

Let:

$$(I)_s = \begin{Vmatrix} I_{1s} \\ I_{2s} \\ \cdots \\ I_{ns} \end{Vmatrix} = [C]^{-1} \begin{Vmatrix} I_1 \\ I_2 \\ \cdots \\ I_n \end{Vmatrix} \tag{30}$$

and, similarly introduce the columnar matrices:

$$(E)_s = (E_{rs}) = [C]^{-1}(E_r) \tag{31}$$

$$(i^0)_s = (i_{rs}^0) = [C]^{-1}(i_r^0) \tag{32}$$

$$(q^0)_s = (q_{rs}^0) = [C]^{-1}(q_r^0) \tag{33}$$

then the equation (28) separates into the n scalar equations:

$$[Z_0+(n-1)Z]I_{1s} = E_{1s} + p[L_0 + (n-1)L]i_{1s}^0 - [S_0+(n-1)S]q_{1s}^0 \tag{34}$$

$$(Z_0-Z)I_{rs} = E_{rs} + p(L_0-L)i_{rs}^0 - (S_0-S)q_{rs}^0 \tag{35}$$

$r = 2, 3, \ldots n$

We then have immediately:

$$I_{1s} = E_{1s}/[Z_0+(n-1)Z] + p[L_0+(n-1)L]i_{1s}^0/[Z_0+(n-1)Z] - [S_0+(n-1)S]q_{1s}^0/[Z_0+(n-1)Z] \tag{36}$$

$$I_{rs} = E_{rs}/(Z_0-Z) + p(L_0-L)i_{rs}^0/(Z_0-Z) - (S_0-S)q_{rs}^0/(Z_0-Z) \tag{37}$$

$r = 2, 3, \ldots n$

Now if we let:

$$(i)_s \div (I)_s \tag{38}$$

that is:

$$i_{rs} : I_{rs} \tag{39}$$

$r = 1, 2, \ldots n$

We may compute the i_{rs} quantities from (36) and (37). We also have the relations:

$$(I) = [C](I)_s \tag{40}$$

and

$$(i) : (I) \tag{41}$$

Hence if we premultiply (38) by $[C]$ we obtain:

$$[C](i)_s \div [C](I)_s = (I) : (i) \tag{42}$$

or finally,

$$(i) = [C](i)_s \tag{43}$$

and we have the various currents explicitly.

VI. Examples

Let us consider the application of the above general theory to specific examples.

Discharge of a Capacitor in One of Two Mutually Influencing Circuits

Suppose that we have two similar circuits each with self-induction L_0 and elastance S_0, but negligible resistance, and that the capacitor in one carries an initial charge q^0. The initial currents in the system and the charge on the capacitor of the second circuit are supposed to be equal to zero. The coefficient of mutual induction is M. The problem is to determine the subsequent behavior of the system.

In this case we have:

$$[Z] = \begin{Vmatrix} Z_0 & Z \\ Z & Z_0 \end{Vmatrix} \tag{44}$$

with:

$$Z_0 = L_0p + S_0/p \tag{45}$$

$$Z = Mp \tag{46}$$

Since we have no impressed electromotive forces and no initial currents, the equations (36) and (37) for this circuit reduce to the following:

$$I_{1s} = -S_0q_{1s}^0/(Z_0+Z) \tag{47}$$

$$I_{2s} = -S_0q_{2s}^0/(Z_0-Z) \tag{48}$$

in view of the fact that $n=2$ and $S=0$.

The transformation matrix C and its inverse for this case is given by:

$$[C]=\begin{Vmatrix}1 & 1\\ 1 & -1\end{Vmatrix} \tag{49}$$

$$[C]^{-1}=\frac{1}{2}\begin{Vmatrix}1 & 1\\ 1 & -1\end{Vmatrix} \tag{50}$$

we thus have:

$$\begin{Vmatrix}q_{1s}^0\\ q_{2s}^0\end{Vmatrix}=\frac{1}{2}\begin{Vmatrix}1 & 1\\ 1 & -1\end{Vmatrix}\begin{Vmatrix}q_1^0\\ 0\end{Vmatrix}=\frac{1}{2}\begin{Vmatrix}q_1^0\\ q_1^0\end{Vmatrix} \tag{51}$$

since the second circuit does not have an initial charge. To simplify the operations, let us write:

$$M=L_0b \tag{52}$$

$$S_0=L_0c^2 \tag{53}$$

We then have the following equations for I_{1s} and I_{2s}:

$$I_{1s}=-c^2pq_{1s}^0/[p^2(1+b)+c^2]=-\frac{1}{2}c^2q_1^0p/(1+b)[p^2+c^2/(1+b)] \tag{54}$$

$$I_{2s}=-\frac{1}{2}c^2q_1^0p/(1-b)[p^2+c^2/(1-b)] \tag{55}$$

If we now make use of the basic transform:

$$p/(p^2+w^2)\div\sin(wt)/w \tag{56}$$

we obtain:

$$i_{1s}=-\frac{1}{2}\frac{cq_1^0}{\sqrt{1+b}}\sin(ct/\sqrt{1+b}) \tag{57}$$

$$i_{2s}=-\frac{1}{2}\frac{cq_1^0}{\sqrt{1-b}}\sin(ct/\sqrt{1-b}) \tag{58}$$

The actual currents in the two circuits i_1 and i_2 are now obtained from the symmetrical-component currents i_{1s} and i_{2s} by the transformation:

$$\begin{Vmatrix}i_1\\ i_2\end{Vmatrix}=\begin{Vmatrix}1 & 1\\ 1 & -1\end{Vmatrix}\begin{Vmatrix}i_{1s}\\ i_{2s}\end{Vmatrix} \tag{59}$$

or hence:

$$i_1=-\frac{1}{2}cq_1^0[(1/\sqrt{1+b})\sin(ct/\sqrt{1+b})+(1/\sqrt{1-b})\sin(ct/\sqrt{1-b})] \tag{60}$$

$$i_2=-\frac{1}{2}cq_1^0[(1/\sqrt{1+b})\sin(ct/\sqrt{1+b})-(1/\sqrt{1-b})\sin(ct/\sqrt{1-b})] \tag{61}$$

We thus obtain the current in the two meshes without solving for the roots of the characteristic equation of the system which in this case is one of the fourth order.

APPLICATION TO THREE-MESH NETWORK

Let us consider an E-symmetric three-mesh network. Let each mesh have a mesh inductance L_0 and mesh elastance S_0. Let the three meshes be coupled together by equal mutual inductance coefficients M.

The network will be considered inert at $t=0$, that is, the mesh currents and mesh charges are zero at $t=0$. At $t=0$, a steady electromotive force E is impressed on mesh one. The problem is to determine the subsequent currents in the three meshes.

For this case, the impedance matrix of the network is given by:

$$[Z]=\begin{Vmatrix}Z_0 & Z & Z\\ Z & Z_0 & Z\\ Z & Z & Z_0\end{Vmatrix} \tag{62}$$

with:

$$Z_0=L_0p+S_0/p \tag{63}$$

$$Z=Mp \tag{64}$$

The general equations (36) and (37) in this case reduce to:

$$I_{1s}=E_{1s}/(Z_0+2Z) \tag{65}$$

$$I_{2s}=E_{2s}/(Z_0-Z) \tag{66}$$

$$I_{3s}=E_{3s}/(Z_0-Z) \tag{67}$$

Now, since the electromotive force impressed in mesh number 1 is steady, we have:

$$\begin{Vmatrix}E_{1s}\\ E_{2s}\\ E_{3s}\end{Vmatrix}=\frac{1}{3}\begin{Vmatrix}1 & 1 & 1\\ 1 & a & a^2\\ 1 & a^2 & a\end{Vmatrix}\begin{Vmatrix}E_1\\ 0\\ 0\end{Vmatrix}=\begin{Vmatrix}E_1\\ E_1\\ E_1\end{Vmatrix} \tag{68}$$

where:

$$a=e^{j2\pi/3} \tag{69}$$

Hence we have:

$$I_{1s}=\frac{1}{3}E_1p/[p^2(L_0+2M)+S_0] \tag{70}$$

$$I_{2s}=\frac{1}{3}E_1p/[p^2(L_0-M)+S_0]=I_{3s} \tag{71}$$

Now if we let:

$$w_1=\sqrt{S_0/(L_0+2M)} \tag{72}$$

$$w_2=\sqrt{S_0/(L_0-M)} \tag{73}$$

then, in view of the transform relation:

$$p/(p^2+w^2)\div\sin(wt)/w \tag{74}$$

we obtain the following expressions for the transforms of I_{1s}, I_{2s}, and I_{3s}.

$$i_{1s}=\frac{1}{3}E_1\sin(w_1t)/\sqrt{S_0(L_0+2M)} \tag{75}$$

$$i_{2s}=\frac{1}{3}E_1\sin(w_2t)/\sqrt{S_0(L_0-M)}=i_{3s} \tag{76}$$

The actual three mesh currents of the system are now obtained by the equation:

$$\begin{Vmatrix}i_1\\ i_2\\ i_3\end{Vmatrix}=\begin{Vmatrix}1 & 1 & 1\\ 1 & a^2 & a\\ 1 & a & a^2\end{Vmatrix}\begin{Vmatrix}i_{1s}\\ i_{2s}\\ i_{3s}\end{Vmatrix} \tag{77}$$

Carrying out the matrix multiplication, we obtain:

$$i_1=\frac{1}{3}E_1\sin(w_1t)/\sqrt{S_0(L_0+2M)}+\frac{2}{3}E_1\sin(w_2t)/\sqrt{S_0(L_0-M)} \tag{78}$$

$$i_2=\frac{1}{3}E_1\sin(w_1t)/\sqrt{S_0(L_0+2M)}-\frac{1}{3}E_1\sin(w_2t)/\sqrt{S_0(L_0-M)}=i_3 \tag{79}$$

We thus obtain the solution to our problem in a most simple manner. It may be remarked that had we proceeded in the conventional operational manner, we would have been forced to determine the roots of a sixth order algebraic equation in order to apply the Heaviside expansion formula. A transformation to symmetrical components avoids all this labor.

VII. Conclusion

The general equations by which the transient analysis of multimesh E-symmetric networks may be carried out have been developed. The introduction of symmetrical component and Laplacian transformations enormously simplify the analysis of this type of networks. Since E-symmetric networks are of great technical importance in many branches of engineering, it is hoped that this contribution to their theory will be of value. The method may be readily applied to all linear dynamical systems exhibiting this type of symmetry whether electrical or mechanical.

The Accuracy of Watt-Hour Meters on Intermittent Loads

M. S. HELM
NONMEMBER AIEE

Synopsis: A watt-hour meter on intermittent loads of a particular character may have a registration error. The magnitude of error is a function of the meter design, the periodicity of the intermittent component of load, ratio of intermittent component to total load, character of intermittent component, power factor of load, and adjustment of the friction compensation.

The registration characteristic of a meter on most types of intermittent load can be predicted from the acceleration and deceleration curves for the meter disk.

THE characteristics of watt-hour meters are dependent upon many diverse factors interrelated in a complex way. The design of the magnetic circuits, the mechanical features of the meter, and the various corrective elements to a large degree are responsible for these diverse factors. Once in service, however, the characteristics of a meter are relatively fixed, except as influenced by the remainder of the circuits with which it is associated.

The nature of the load which is to be measured by the meter may have an important effect on the characteristic performance of the meter. Loads may vary continually in magnitude or be intermittent with the period of cyclic variation from a few cycles to many minutes or hours. Such intermittent loads may cause factors which are usually of relatively minor importance to have considerable influence on the meter accuracy. Since these factors are interrelated, it is difficult to separate them experimentally, and only their combined effects have been studied.

In the usual application of watt-hour meters, the intermittent nature of the load will affect only those factors which depend upon the magnetic effects produced by the current elements or series coils, the potential element being energized at all times, thus making its effects constant. However, some adjustments of the meter which are independent of the series coil may affect the meter performance because of the interdependence of those factors and their influence on the common sections of the magnetic circuit.

The results of this study are given in curve form and are representative of several meters operating under the same load conditions. A careful study of the starting and stopping characteristics was made photographically. These results were verified by actual load tests.

Results of Study With Discussion

The registration of a watt-hour meter is a direct measure of the total angular travel of the meter disk. This angular travel, in turn, is a function of the angular velocity of the disk and time. The angular velocity of the disk for a given load is dependent upon the mechanical and geometrical factors of the moving system and the summation of the various component torques (driving and retarding) acting on this moving system.

It has been shown that the mechanical and geometrical factors for a given meter are essentially constant. As indicated in the appendix, the various component torques are constant when the load on the meter is constant, but for a variable load, the various component torques do not remain constant during the transitory periods. Certain torque factors which are present during the acceleration period of the meter disk may not be present during the deceleration period. The relative magnitudes of these changing torques will determine the meter accuracy during the transition period from one load value to another.

Figure 1 shows the accelerating and decelerating characteristic curves for a typical modern meter.* These curves are representative of those obtained from a stroboscopic photographic recording of the meter-disk travel during the period of change from rest to constant angular velocity and from constant angular velocity to rest. It will be noted that the slope of the constant-velocity sections changes in accordance with the different loads. Data for these curves were obtained by scaling angular travel of the meter disk from successive photographs of the disk obtained by means of a stroboscopic camera. The time interval between successive photographs was controlled accurately. The time or angular travel necessary for a disk to attain constant velocity was obtained by drawing a tangent to the curve at a slope corresponding to the velocity attained.

In an ideal meter in which no torque component is a function of higher than the first power of the disk angular velocity (appendix) and in which the ultimate disk velocity is directly proportional to the load, the time required to attain any given per cent of ultimate velocity is not a function of the load. In a practical meter, however, these conditions are not fulfilled although they are approximated closely. The position of the anticreep slots at the start of the acceleration period, the flux density in the various portions of the magnetic circuit, reactions of disk currents on the distribution of the flux in the various paths, and the variation of the friction torque with disk velocity are some of the factors which can produce small effects in a practical case. The accurate determination of the time required to attain steady-state condition is not necessary, an approximation being sufficient to indicate the character of intermittent loads which may give rise to registration errors. The graphical method of determining the point of tangency has inherent errors larger than the probable error due to the causes listed above.

The time required for the disks of meters of different designs to reach a constant angular velocity differs, the limits being approximately 0.2 second and 0.4 second. The time required for the disk to reach rest from the constant angular velocity corresponding to rated load is from 0.3 to 0.4 second. These variations between meters of different designs can be attributed to the fact that the components of torque are not in the same proportions in the different meters. It should be noted, however, that the time required is of interest only in the examination of a load cycle. The accuracy with which the meter integrates a load over a cycle depends upon the total disk travel during the cycle and not upon the time required for that travel.

If a constant load is placed on a meter

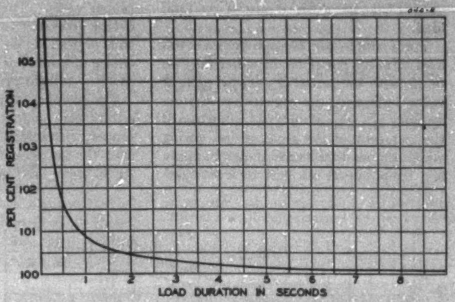

Figure 2. Effect of load duration on watt hour meter accuracy for 200 per cent load a unity power factor

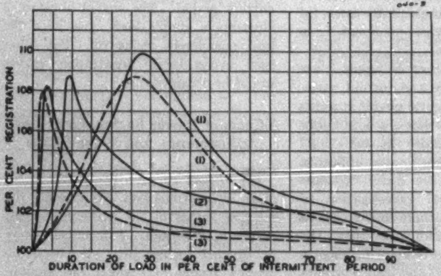
a sufficient time to allow the meter disk to start from rest and attain constant angular velocity and then is removed for the length of time required for the meter disk to return to rest, the total angular travel of the disk should be a direct measure of the energy involved in the load cycle. This total disk travel should be equal to the product of the constant velocity and the time the load is applied if this registration is a correct measure of the energy. During the period of acceleration up to the velocity corresponding to the load value, the disk has lost a definite number of degrees of travel since it must start from rest and its average velocity during this accelerating period is less than the constant value corresponding to this load. After the load is removed, the disk decelerates to rest and gains a definite number of degrees of travel. If the number of degrees lost during the acceleration period does not equal the number gained during the deceleration period the meter registration is in error. This error in registration will be positive or negative in accordance with too large or too small a gain in disk travel at the end of a load cycle compared to the beginning. It will be indicated later that this error is influenced by the design of the meter and its adjustments for constant load accuracy.

If the load exists for a longer time than is necessary for the disk to attain the velocity corresponding to the load, the disk will travel at constant velocity for the time in excess of that required to reach this load velocity. The disk travel to rest after the load is removed will be the same for a given disk velocity regardless of the time the meter has been running at this velocity. The error in registration (degrees of travel) will be the same for each load cycle, but the per cent error in total registration will approach that for a constant load.

Figure 3. Comparison of predicted and test curves of watt-hour meter accuracy for intermittent loads of different periods



Predicted curves are in solid lines
Test curves are in dotted lines

Curve 1—8-cycle period
Curve 2—35-cycle period
Curve 3—100-cycle period

The effect of the length of the constant velocity period on the total registration of the meter is shown in figure 2. This curve is obtained from curves such as given in figure 1. The curve of figure 2 is for approximately 200 per cent load, unity power factor on the meter. As the constant-velocity interval is increased for a given load, the per cent error is reduced. It will be noted that for load durations less than one second, the meter error, caused by intermittent load, is one per cent or more and, for very short duration loads, will exceed five per cent. If the load duration is greater than four seconds, the intermittent load cycle causes an error less than one-fourth per cent. This error is within the limits of commercial meter accuracy.

For practically all types of intermittent loads, the approximate registration characteristics of the meter may be predicted, from the acceleration and deceleration curves (figure 1) for the meter. These characteristics should be at the power factor and with the same wave form as would be encountered in the circuit under consideration. For any load-variation cycle in which the load decreases to zero the approximation may be very close if the acceleration curves are known for each value of load and the deceleration curve is known for the greatest value of load to be considered in the group of loads studied. The degree of approximation (in predicting the registration characteristics) for other load cycles depends upon the relative value of the variable and fixed components of the load. The approximation is least accurate when the fixed component becomes a major part of the total load.

For a simple case of approximately full load of unity power factor either fully on or off, with the period of the load cycle of value indicated, the registration characteristics of a typical meter as a function of the per cent of the total period during which the load exists are shown in figure 3. These curves are derived from characteristics such as given in figure 1. Curves from experimental data for the same meter in a circuit with a load having periods of 8 and 100 cycles are shown for comparison.

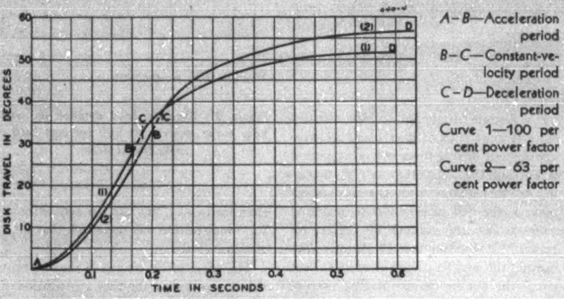


Figure 4. Acceleration characteristics of a typical watt-hour meter for 200 per cent load at two different power factors

With the characteristic curves for the meter available, for the loads chosen, such curves as those in figure 3 may, for simple load cycles, be predicted with ease. Beginning with the disk at rest the acceleration disk-travel curve is drawn for the length of time corresponding to the "on" portion of the load cycle. This curve is then extended by use of the deceleration disk-travel curve from the point on that curve having the same slope as the acceleration curve at the end of the first "on" portion. The deceleration curve is used for a time corresponding to the "off" portion of a load cycle. The acceleration curve is then applied as before except that the velocity at the end of the previous "off" period must be used to determine the initial conditions for the new "on" period. Successive "on" and "off" conditions must be assumed until the disk travel in any single load cycle becomes a constant value. This travel is compared with the proper value (constant velocity times the "on" time) and the registration noted as compared to the proper value. The number of these load cycles necessary to have "steady state" will depend upon the meter and the choice of load cycle and may be as many as 10 or 15 load cycles.

For complex load cycles the same procedure can be followed except that the proper characteristic curves must be used for the acceleration portions of the travel curve, and deceleration curves for partial removal of loads should be available. None of these deceleration characteristics for partial removal of loads has been included in the data of this investigation.

The experimental check was obtained by applying intermittent loads of a definite nature and comparing the actual registration of the meter for a known number of cycles "on" with the registration of the meter for the same number of cycles "on" for a continuous load of the same magnitude, power factor, and wave form. These check load cycles were chosen to correspond to those for which the errors were predicted from characteristic curves.

The predicted curves of figure 3 are for sinusoidal voltage and current variations. The experimental circuit currents correspond closely to that of a continuous welder. The harmonics in such load currents may be expected to influence the registration of the meter to some extent. Experimental investigation of this factor by the authors in the case of continuous loads indicates that the effects of such proportions of harmonics as are present in those load currents will not introduce an appreciable error in registration. The influence of this factor on the registration of a meter on intermittent loads should be very nearly the same as for constant loads having the same wave shape since the same torque factors would be affected by the harmonic components. For loads of short periodic duration, the effect of the corrective adjustments also is important. The light load compensation should be carefully adjusted, otherwise its effect will influence the shape of the registration curve. See paragraph (*b*) of the next section.

It will be noted that the maximum error in registration of the meter, used as an illustration, occurs when the duration of the load is from two to four cycles. Certain welder controls are commonly set for this period of operating time in order to give the proper working conditions for the materials being processed. It will be noted that the magnitude of the predicted maximum error is nearly independent of the period of load. This is borne out by the experimental results. Tests have indicated that, in the older designs of meters, this error is greater than in the more modern meter designs. This, no doubt, is caused by a different relationship between the various torque components in these classes of meters.

In some of the meters tested, when adjusted within the limits of accepted commercial accuracy, this maximum error was as great as 20 per cent. More than normal care in adjusting the meters resulted in the marked reductions in the maximum error.

The registration error due to intermittent load must approach zero as the acceleration portion of the load cycle approaches zero or 100 per cent of the load cycle. At some other value of the duration of load the error must be a maximum. The per cent of the intermittent period at which the maximum error occurs depends upon the design of the meter and the length of the intermittent period. The curves of figure 3 illustrate a simple load cycle with the load completely on or off. For other load cycles other registration curves would be obtained.

Effects of Power Factor, Light-Load Adjustments, and Wave Shape

(*a*) *Power Factor*. The power factor of an intermittent load will influence the relative values of the accelerating and decelerating torques. This influence may be divided further into (1) effects on driving torque, (2) effect on friction-compensating torque, and (3) effect on current-damping torque. The exact influence of power factor on each is not known quantitatively but it may be shown (see appendix) that these three torque components may be affected. The driving torque per ampere will be decreased as the power-factor angle is increased. This in turn may affect indirectly the friction compensation because of a new resultant flux per unit of driving torque. The new resultant flux may be shifted in time phase relative to the original flux, which may cause a change in the magnitude of the friction-compensating torque.

The effect of power factor on the current-damping torque is a function of current-coil flux. The flux will increase as the current increases but in a proportion which is dependent on the properties of the magnetic circuit. The effect at normal current values will be approximately in proportion to the current change per unit of power.

The net effect of small changes in power factor alone on the intermittent-load characteristic of the meter is ordinarily a minor one, because of the small net changes which occur in the total torques. Figure 4 shows the starting and stopping characteristic curves for a meter at two widely different power factors. The curve at the lower power factor indicates a longer time required to reach constant velocity from rest for the same load but the decelerating periods are the same. The elapsed time for a complete start-stop cycle is greater at the lower power factor and as a result the total travel of the disk is greater for the complete cycle. This increased time for a complete start-stop cycle will affect the meter performance on very short interval loads where the meter does not reach the true load velocity. For the loads of longer duration the error in starting and stopping is decreased and it is quite possible to have a meter with a combination of torque values which will give correct registration at some low power factor. Depending upon the adjustments of a meter, low lagging power factor loads may cause the registration error to become negative.

(*b*) *Light-Load Adjustments.* The curves which have been shown (figures 1, 2, 3, and 4) have been determined with the light-load adjustments as carefully adjusted as possible for all the meters used in these tests. The influence of this light-load compensation and how it can affect the meter performance on intermittent load is indicated by the registrations at three different positions of the light-load compensator for the same meter load. This influence is indicated in figure 5. The three points on the curve for this periodic load (three cycles on and five cycles off) are for the compensator positions of (1) ready to creep backward, (2) mid-position of compensator, and (3) ready to creep forward. The mid-position of the friction compensator corresponds very closely to the actual position used when this meter was in the original test circuits. Several test runs were made with the compensator at various positions and for intermittent loads of different periodic durations. It can be inferred from figure 5 that the component of torque from the compensator will be of great importance for loads of short periodic duration but will be less important as the period becomes longer. It is believed that more than ordinary care should be exercised in adjusting the compensator if the meter is to be used on a circuit which has a transitory load of major importance and of comparatively short periodicity.

(*c*) *Wave Shape.* Care was exercised in making comparisons between the performances for different load durations, that the wave shapes of the current and voltage were constant. The study of the effects of wave shape is separate and apart from this load study, but tests have been made which show that wave shape will influence the registration of a meter and for that reason only performance curves for the same wave shapes were compared in determining the meter accuracy.

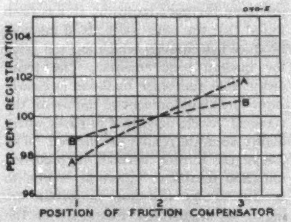

Figure 5. Effect of friction-compensator position on watt-hour meter accuracy for intermittent loads of short duration

A–A—One cycle on and seven cycles off
B–B—Three cycles on and five cycles off

Conclusions

1. The stroboscopic photographic data of the meter accelerating and decelerating characteristics can be used to predict with a good degree of accuracy the performance characteristics on most types of intermittent load. This is indicated by the comparison of the predicted and the actual test curve shown in figure 3.

2. The relative effects of the various torques influence the registration of a meter. If the speed of the disk is low, as in the present-day meter, the retarding torques will maintain a fairly uniform relationship. The current-damping torque has less relative effect in the modern meter and as a result, the accuracy on intermittent load has been improved.

3. The character of the load cycle, that is, the time the load is on and the time the load is off, influences the registration of the meter. Tests indicate that the conditions for maximum error occur at two to four cycles of accelerating period. This maximum error may be as much as 20 per cent. The off period apparently is not so important.

4. The adjustment of the light-load compensation is extremely important and care must be taken to be certain that there is minimum friction in the moving system of the meter, in order that friction-compensation-torque value may be minimized. If the adjustment is such that the meter is on the verge of creeping, an error up to 30 per cent may be obtained.

5. The variation of an intermittent load may be of a small magnitude in comparison with the average value of the load. In this case the influence of the load variation will be negligible.

6. Tests indicate that the load power factor influences the registration error. However, the damping effect of the current flux is relatively small in the modern meter, and the power factor of the load does not affect the meter accuracy on intermittent loads as much as in meters of older design.

7. The increased overload rating and increased ratio of driving torque to the moment of inertia of the moving element have decreased the accelerating time for a given load change. This improvement has decreased the meter error on intermittent load from the values found in the older designs of meters.

8. For metering loads which are continually transitory in nature, it is suggested that present-day meters be used and that a careful study of the load be made. Loads, such as electric welder and flashing electric-sign loads, should be carefully studied before being metered as a single load on a meter.

Appendix

When a watt-hour meter is recording a constant load at a constant speed, the total driving torque equals the total retarding torque. The relationship can be expressed in equation form as:

$$(T_D+T_L)-(T_M+T_P+T_C+T_F)=0$$

where

T_D = driving torque produced by the interaction of the potential-coil and current-coil fluxes
T_L = driving torque of the light-load (friction) compensator
T_M = retarding torque of the permanent magnets
T_P = potential-flux retarding torque
T_C = current-flux retarding torque
T_F = retarding torque of friction

In order to indicate the relative importance and effect of each term the controlling factors of each torque are indicated. Thus, the torque equation becomes:

$$k_1 f[\underbrace{(f)\phi_P\phi_C \sin\alpha}_{1}+\underbrace{(f)\phi_P{}^2 \sin\beta}_{2}]-$$
$$\frac{k_1}{2}f_d[\underbrace{(f)\phi_M{}^2}_{3}+\underbrace{(f)\phi_P{}^2}_{4}+\underbrace{(f)\phi_C{}^2}_{5}]-$$
$$\underbrace{[k_f(f)f_d+F_0]}_{6}=0$$

Part 1 = T_D expressed as a function of potential flux, current flux, and the angle of displacement between them
Part 2 = T_L expressed as a function of the square of the potential flux and the angle of displacement between the resultant flux and potential flux
Part 3 = T_M expressed as a function of permanent-magnet flux
Part 4 = T_P expressed as a function of potential flux
Part 5 = T_C expressed as a function of current flux
Part 6 = T_F expressed as a function of disk speed plus a friction-torque component independent of speed
k_1 = constant which includes the geometrical constant, gravitational constant, etc.
f = circuit frequency
f_d = rotational speed of the meter disk
k_f = frictional constant for the disk
F_0 = friction constant

During the interval of transition from one load value to another, the torque equation must contain another term. This term, which may be called the transition torque, may be a driving or a retarding torque and will be of sufficient magnitude to balance the torque equation at every instant. The transition torque will be a retarding torque during an increase in load and a driving torque during a decrease in load. The rate of change of the transition torque during a transition interval will depend upon the changes in the other components in the torque equation. Since the retarding torques are a function of disk speed and the meter registration is $\int f_d dt$, the meter registration for loads which are for the most part transitory in nature, will depend on the effect of the transition torque.

ARTHUR J. SCHUMER
ASSOCIATE AIEE

THE practical work of inventing the polyphase induction motor, by Nikola Tesla and Galileo Ferraris, was followed by farseeing analytical studies of motor operation. Masterly theoretical analyses of the induction-motor circuit were made by B. A. Behrend, Alexander Heyland, and others. These men, through their insight and understanding, were able to devise ingenious methods for theoretically predetermining operating characteristics of induction motors by employing readily determined constants. For many years these methods of predetermination were accepted and used in practical work. However, as knowledge has expanded and a higher degree of accuracy becomes requisite, it has been found that the older methods of analysis produce inaccuracies which are too great for modern requirements. The trend away from the older methods is clearly shown by abandonment of the use of the classical "circle diagram" in cases where highly accurate results are desired. The use of the former methods of predetermination results in inaccuracies due to several factors, the most important being: (*a*) unjustified treatment of the exciting current, (*b*) the assumption that circuit parameters are constant when they are not, and (*c*) failure to consider the stray load loss. The errors resulting from wrong assumptions may not prove serious for light loading of the motor, but discrepancies increase as load and slip become greater.

A study is made in this paper of the factors which produce rotor losses and corresponding torque in induction motors. A method of accurately analyzing this problem is given, based upon elemental principles and including important effects which have been omitted from previous studies. In order that correct principles may be applied and accurate results obtained in practical determinations, a complete test procedure with required calculations is outlined. The principles developed are illustrated by tests on a selected motor. However, these principles are general in nature and are not limited in their application by the type or size of induction motor. In approach and general treatment of the subject the analysis differs from previously accepted methods. This difference is pronounced in two important respects. In the first place, the analysis gives consideration to the effects of stray load loss. In order to predict results the laws of variation of this loss are investigated and it is shown that it varies as the square of both current and motor speed. The fact that this loss plays a highly important part in the production of motor torque at all higher values of slip is made clearly evident. Secondly, a study is made of the rotor-resistance loss, showing that variations in the value of rotor resistance become a most important factor in such considerations. In this connection, the rotor effective resistance is studied and its variation with the frequency of the rotor circuit is determined. The manner in which the resulting loss operates to produce motor torque is shown clearly by the analysis. Finally, the net over-all torque is derived by combining the separate components. The results show great discrepancies when compared with conventional values.

Investigation of induction-motor characteristics was made over a range of slip extending from zero up to a value of 200 per cent. Accurate determinations show that the actual torque of a motor at high slip may have a value of two or three times that calculated by conventional methods. Discrepancies of this nature have been noted by other investigators[1] and are of such magnitude as to demand

attention. In modern applications a motor may be reversed by plugging, at which instant the slip is 200 per cent. In such reversing cycles both the heating of the motor and the torque developed throughout the cycle become important considerations. The extent of the heating is determined by the magnitude of the losses and the time required to reverse the motor, the latter depending upon the torque developed. The magnitude of instantaneous torque also becomes an important factor in shaft design. In addition, the results of the investigations with which this paper is concerned have a direct application in problems of polyphase unbalance. In applying the symmetrical-component method of analysis, the action of the negative-sequence current is made truly predictable through the application of the principles herein deduced.

Experimental Investigation

In order to make a practical study of motor characteristics, tests were made on an ordinary squirrel-cage induction motor. To insure that the effects of stray load loss would not show themselves in undue proportion, a motor was selected in which this loss was reasonably low, being 2.08 per cent of full-load input at rating. It was fortunate that considerable test information was already available, this motor having been used in previous tests.[3,4] The motor was rated at ten horsepower, 550 volts, 10.3 amperes, three phase, 60 cycles, and 1,750 rpm. The stator had 48 teeth with semiclosed slots, and the rotor 57 teeth with coffin-shaped slots.

The motor was directly connected to a calibrated d-c machine by a flexible coupling. Power from a three-phase a-c source, having balanced voltage which could be adjusted to any required value, was applied to the stator. Instruments were so arranged that both electrical power input and output could be accurately measured. Measurements were taken at several values of current while the speed was held constant and observed by the use of a stroboscope. Motor current was adjusted to any desired value by control of the applied three-phase voltage. Measurements were made over a range extending from rated current to between three and four times this value. The stator resistance was measured by a resistance bridge immediately following each run, and the friction and windage loss of the two coupled machines was measured at the same time by driving through the d-c machine. Complete runs were made for speeds of 100, 80, 50, and 25 per cent of synchronous speed in the reverse direction to the stator field, for zero speed with locked rotor, and for 25, 50, and 80 per cent of synchronous speed in the same direction as the stator field.

Stray Load Losses

For all points at synchronous speed in the reverse direction values of stray load loss were calculated by the reverse-rotation method.[4] Each point was obtained by taking the difference between the net mechanical power input to the rotor and the net electrical power input to the rotor received from the stator. The results are shown by curve *A* of figure 1 where the loss is plotted as a function of stator current on logarithmic cross-section paper. Curves *B*, *C*, and *D* in this figure show the stray load loss for speeds of 80, 50, and 25 per cent of synchronous speed respectively. The three latter curves are obtained in the same manner as curve *A* except that care is taken to subtract the appropriate value of net rotor power supplied by the stator for each speed. These amounts are 0.8, 0.5, and 0.25 times the rotor power received from the stator for corresponding speeds.

The black points of curve *C* were obtained by operation of the machine at 0.5 speed in the same direction as the stator field (that is, for ordinary motor action). In this case the stray load loss is obtained by subtracting the measured value of net mechanical power developed from one-half of the rotor power received from the stator. The close agreement between values obtained in this manner with those obtained from reverse rotation at the same rotor speed indicates the degree of accuracy of the reverse-rotation method at this particular speed. This substantiates the assumption that the stray load loss is not affected by the direction of rotation.

Curves *A*, *B*, *C*, and *D* of figure 1 all have a slope of two indicating that the stray load loss varies as the square of the current for all values of speed.

In order to determine the law of variation of stray load loss as a function of motor speed, values of the loss at different speeds were taken from the curves of figure 1 at the point of rated current. In figure 2 these quantities are plotted as a function of motor speed on logarithmic cross-section paper. The fact that the resulting curve has a slope of two indicates that the stray load loss varies as the square of the rotor speed for constant current.

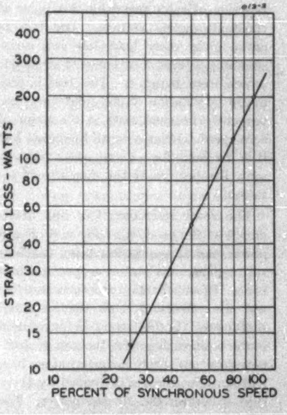

Figure 2. Stray load loss as a function of speed at rated current

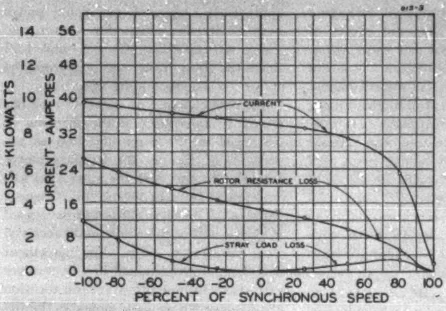

Figure 3. Stator current and losses at one half voltage as function of rotor speed

Motor Characteristics at One-Half Voltage

Since it was impossible to obtain measurements at full voltage for the speeds selected without damaging the motor due to overheating, the characteristics of the motor were first obtained at one-half rated voltage. The top curve of figure 3 shows measured stator current as a function of rotor speed for this value of constant applied voltage. The bottom curve gives stray load loss for corresponding speeds and currents as determined from figure 1. This loss is produced by rotation of the motor and consequently becomes zero at the point of zero speed. Being a tooth-frequency loss it is the same for a given speed and current, irrespective of the direction of rotation.

The rotor resistance loss was determined as the product of slip and air-gap power, the air-gap power being taken as stator input less stator copper and iron losses. In addition the rotor resistance loss was also calculated from the measured shaft power. In this latter case for rotation in the positive direction, the sum of shaft-power output, friction and windage loss, and stray load loss was divided by (1 — slip) to obtain the air-gap power. For rotation in the reverse direction the sum of friction and windage and stray load loss was subtracted from the mechanical power input to the shaft and the difference divided by (slip — 1) for obtaining air-gap power. The fact that the values of the rotor resistance loss obtained from the stator electrical power input and from the mechanical shaft power showed good average agreement indicated that the iron loss due to the stator leakage flux was of negligible importance for these calculations.

The rotor resistance loss thus obtained is of the nature of an *effective* resistance loss and includes all components of loss that occur as a result of the slip-frequency rotor currents. In addition to the slip-frequency copper loss component, there may be components of eddy-current losses in the rotor circuit and slip-frequency iron losses caused by the air-gap and rotor-leakage fluxes. This effective resistance loss of the rotor is shown by the middle curve of figure 3.

Each loss produces its own value of torque. The rotor effective resistance loss results in a force from the reaction of slip-frequency currents in the rotor and the air-gap field rotating at synchronous speed. Thus the torque can be calculated from the power loss and the difference in speed of the rotor and the synchronous field (that is, the slip speed). The dashed-line curve of figure 4 shows the torque resulting from the rotor effective resistance loss. At small values of slip a small loss produces a large torque while at high slip it takes a large loss to produce the same torque. The torque resulting from the rotor resistance loss is the only component of torque which in the past has been considered in conventional calculations. The curve of rotor resistance loss shown in figure 3, and corresponding torque of figure 4 differ from customary calculations in that they are derived from actual measurements, instead of being calculated from a value of rotor resistance which is usually considered as constant.

The stray load loss produces a drag on the rotor which in this respect is similar to friction and windage effects. Thus the torque resulting from it has a negative value over the complete range of positive directional speeds, reducing the available torque of the motor. However, during reverse rotation the torque from this loss tends to stop the motor, thus operating in the same direction as the torque from the rotor resistance loss. Consequently both quantities are considered as positive over this range of speeds. The torque resulting from stray load loss is shown by the bottom curve of figure 4. It is important to note that the stray-load-loss torque occurs at the speed of the rotor. While this loss (as shown in figure 3) does not appear large it may produce a relatively larger torque. If for example we consider relative values at the point of synchronous speed in reverse direction, we find the stray load loss is less than one-half the value of rotor resistance loss. However, while the stray load loss results from forces occurring at the rotor speed, the rotor resistance loss is produced by reaction with the stator field which is moving at double synchronous speed with respect to the rotor. Since the torque for any rotor loss varies inversely as the speed of the force reaction producing it, the difference in speed results in torque from the stray load loss which is nearly equal to that from the rotor resistance loss at this point.

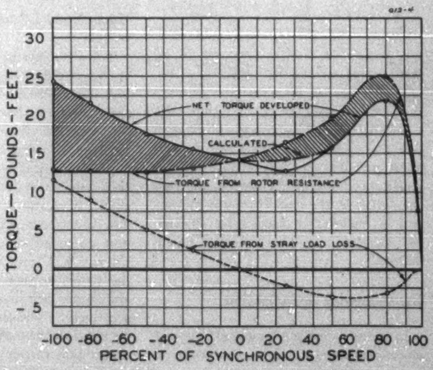

Figure 4. Torque curves for one-half-voltage operation

The combination of the torque from stray load loss with that from the rotor resistance loss gives the net torque available to drive the rotor. Stray load loss causes a reduction in torque over the range of direct rotation which is shown by the shaded portion to the right of the point of zero speed in figure 4. For reverse-rotation operation the torque from stray load loss causes a marked increase in the net torque tending to stop or reverse the motor. This effect is shown by the shaded portion at the left of the diagram. It is significant that the measured shaft torque, after being corrected for friction and windage, gives a net value which is in complete agreement with the resultant of the two components, with the exception of a short portion of the curve between zero and one-half speed in the positive direction. The discrepancy over this range is considered to be the result of torque effects caused by harmonic components of flux. The full-line curve marked "net torque developed" in figure 4 was obtained from measured output.

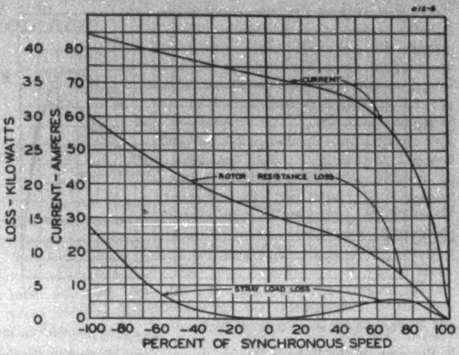

Figure 6. Curves of current and losses at full voltage

Rotor Effective Resistance

All losses which occur at slip frequency in the rotor have been considered as rotor *effective* resistance loss. This loss was found to vary as the square of the current for a given frequency but to have different values for the same current at different frequencies. This indicates that the effective resistance of the rotor is not constant. Its value for one phase of an equivalent wye-connected rotor was obtained by dividing the total loss by three times the square of the rotor current. The equivalent effective resistance for each phase of the rotor circuit is shown by the curve of figure 5. Since the total loss includes among its components hysteresis and eddy-current iron losses due to the rotor leakage flux, it could not be expected that the effective resistance would remain constant at different rotor frequencies.

The curve shows that the rotor resistance increases appreciably at higher frequencies, being about 1.68 times as large at 120 cycles (synchronous speed in reverse direction) as it is at very low frequencies. At zero speed (locked rotor) the resistance has risen to 1.18 times its lowest value.

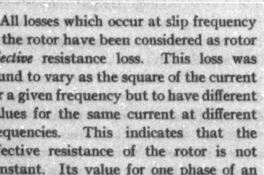

Figure 5. Curve of rotor resistance per phase as a function of frequency in the rotor circuit

It was found that the resistance could be expressed by a mathematical equation of the following general form

$$R_{\text{eff}} = a + b\epsilon^{mf}$$

where R_{eff} is rotor effective resistance in ohms per phase, f is frequency in cycles per second, ϵ is the base of natural logarithms, and a, b, and m are constants. Supplying values of the constants for this particular case gave the equation

$$R_{\text{eff}} = 0.74 + 0.103\epsilon^{0.0156f}$$

Characteristics at Full Voltage

Knowing the value of rotor effective resistance and the laws of variation of stray load loss with current and frequency, motor characteristics at full voltage can be easily calculated if current values can be determined. The latter were obtained by extrapolation of current-voltage curves taken at constant speed. A slight curvature in such curves, extending up to a point of approximately twice rated current, indicated small effects due to tooth saturation. For higher values of current the curves become straight lines permitting accurate extension to the point of rated voltage. Current values obtained in this way are shown by the top curve of figure 6. The rotor resistance loss then was calculated using values taken from figure 5, and the stray load loss was obtained by extrapolation of curves of figure 1. The resultant loss curves are also shown in figure 6.

Torque values corresponding to each of the losses were obtained in the manner previously described for the one-half voltage characteristics. The resultant net torque curve was then found by combining the torque components as in figure 4. This net torque developed at full voltage is shown by the full-line curve of figure 7. Stray load loss has a more pronounced effect in altering the torque curve at full voltage than at one-half voltage due to the fact that this loss and its corresponding torque vary as the square of the current. The full-voltage torque curve is obtained on the assumption that both rotor and stator resistance remain unchanged from heating by the high currents, which would not be the case if such currents were maintained for more than a very short period. This torque curve is quite accurate except over the range of motoring speeds extending from zero to approximately one-half synchronous speed. Over this range harmonic fluxes may cause changes in torque which are difficult to predict.

In order that this speed-torque characteristic might be compared with the curves calculated in the conventional way from constants measured under locked-rotor conditions the latter are also given. The dotted-line curve marked "theoretical—*A*" is derived from circuit parameters measured at zero speed with current corresponding to the point of rated voltage. Consequently it agrees with the actual curve at this point. The dashed-line curve labeled "theoretical—*B*" is computed from locked-rotor circuit parameters taken at the point of rated current. The rotor effective resistance was the same for these two cases, but the combined leakage reactance was larger for the case of rated current. This latter difference was due to magnetic saturation

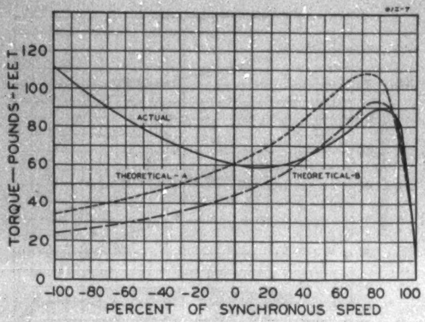

Figure 7. Comparison of actual torque to be expected with torque curves computed from locked-rotor measurements

in the path of the leakage flux as above mentioned. This difference in value of leakage reactance produces very different theoretically computed speed-torque curves. However, the important fact to note is the pronounced difference between the actual torque and that obtained by calculations from locked-rotor data. At synchronous speed in the reverse direction the actual torque developed is more than three times that computed by conventional methods.

A New Accurate Method

The ability to obtain accurate characteristics of induction motors without actually measuring them is most desirable. It is evident that if such predetermination is to be made it will require more information than can be obtained from locked-rotor and no-load tests. The effects of stray load loss and the variation of rotor effective resistance as a result of change in rotor frequency must be taken into consideration. These effects may be included readily by adopting the following procedure.

In addition to the customary locked-rotor and no-load tests two additional tests become necessary. These are a reverse-rotation test and an ordinary load run. The reverse-rotation test has been fully specified in a previous paper[4] which should be referred to for a complete description. This test, which is made at synchronous speed in reverse direction, should include data over the range of current from rated value up to as high an amount as can safely be used without overheating the machine. The test will give stray load loss as a function of current at synchronous speed. By application of the law that this loss varies as the square of current and speed its value can be calculated for any required condition. The rotor effective resistance loss can be readily obtained by taking twice the air-gap power for points of test. Knowing the resistance loss for given values of current the rotor effective resistance can be calculated readily at double frequency. A current-voltage curve can also be plotted, which when extended as a straight line above the point of saturation will give the current for rated voltage.

The locked-rotor test would be made as in the past over as large a range of current as possible. The results should be shown in a current-voltage curve which may be extended as above to the point of rated voltage. Impedance per phase can be calculated from voltage and current at this point. Then by using the average value of input effective resistance a value for total inductive reactance can be obtained. Measurement of stator resistance will permit determination of the rotor resistance by separation.

An ordinary load run should be made in which the slip is measured with high accuracy. Output power is not an important measurement as air-gap power can be obtained by subtracting stator copper and iron losses from measured input power. Multiplication of air-gap power by slip will give the rotor resistance losses. Rotor current is found by vector subtraction of the exciting component from the stator current. Rotor resistance per phase is then computed from rotor losses and rotor current.

We now have three points of rotor effective resistance, that is, points at low rotor frequency, locked rotor, and double frequency. This will permit the drawing of a curve of rotor resistance similar to that of figure 5. It now remains only to find current values for rated voltage in order to determine rotor resistance loss and stray load loss. Current at no load and at rated load has been obtained by measurement. Also, values of current are available for the locked-rotor point and for that of synchronous speed in reverse direction. This leaves points of current between that of zero speed and full load to be determined. Values of rotor resistance over this range are available from the curve. By assuming values of slip and dividing the corresponding rotor resistance by it we obtain the equivalent circuit secondary resistance. The total input resistance is obtained by addition of primary resistance to secondary equivalent resistance. This may be combined with the input reactance obtained from the locked-rotor test to find the total input impedance. It has been found that leakage reactance remains nearly constant over this range of speeds, but any slight variation therein is not serious because of the greater importance of the rotor equivalent resistance. Knowing the equivalent impedance, current values can then be calculated for any given speed. As the current curve appears to be almost a straight line between zero speed and synchronous speed in reverse the complete current curve can now be drawn. Loss curves can be determined and corresponding torque curves obtained. Resultant torque is then found by combination of the component values. The experimental work necessary to obtain accurate determinations as above described is not increased greatly over that required for conventional determinations, the main additions being the reverse-rotation test and the measurement of slip for a corresponding value of power input under load. Calculations are simple and straightforward with the separate steps following in a logical manner.

Discussion

Discussion will be found in the 1940 annual Transactions volume and in the 1940 "Transactions Supplement" to Electrical Engineering.

Control of Inductive Interference to Telegraph Systems

J. W. MILNOR
FELLOW AIEE

THE tendency of power-supply and distribution systems to cause extraneous currents to flow by induction into telegraph lines, has presented a diversity of problems which are of concern to both interests. No one solution is found to be of general application; rather it ordinarily is necessary that each situation be made the subject of individual study.

In different instances it may be most economical to control the interference by attention to the design of the power system, or by choice of routes for each line, or by mitigative equipment applied directly to the telegraph system. The present paper will be limited in scope to the third class of control methods; it will describe various special devices which may be applied in different cases to the telegraph circuit for reducing the power interference, with indications of their accomplishments and of their limitations.

The discussion herein is in particular reference to interference which tends to continue during normal working of the power systems, although some of the devices referred to are also effective in removing those more severe surges which occur at times of power line or equipment failures. Extraneous voltages are induced where power and telegraph lines parallel, and tend to reduce the capacity and the dependability of the telegraph. An exposure one mile in length at a separation of a few hundred feet may result in a small or a severe interference dependent upon the nature of the power system and type of telegraph circuits. The voltages are caused by the magnetic field created by the power system, which interlinks the telegraph wires. The electric field from the power line is seldom of importance.

Usually the fundamental frequency of the power system, 25, 50, or 60 cycles, is of chief concern. Sometimes the third harmonics of these create interference. In our experience no cases have occurred where harmonics higher than the third have created interference to physical telegraph circuits. The interference is most severe where some part of the power current flows in the earth, as may be the case when neutral points are grounded, or as always occurs in electric-railway practice.

As distinct from power practice the telegraph circuits ordinarily are not worked at any standardized frequencies. The assigned speed of each telegraph depends upon the amount of business between the terminuses; economical considerations require that where the business is sufficient to justify, the speed shall be the maximum practical working capacity of the line between the points.

The consideration that in this country there are many situations where large volumes of telegraph business exist between cities widely separated, has created a strong incentive to develop the maximum telegraph line speeds. As part of this objective Western Union has endeavored to survey every practical method for minimizing the effects of power induction.

Review of Theory of Telegraph Transmission

The transmission of intelligence by telegraph requires that current, controlled in accordance with a code and representing the message to be sent, shall be impressed on the line and shall be correctly interpreted at the distant end of the line. The discussion herein will be in particular reference to the multiplex printing telegraph system, which serves for the more important message circuits and which utilizes probably the most efficient available code. However, the fundamental problems of line transmission are the same in all telegraph systems.

In the multiplex each letter or figure is represented by a code character consisting of five units of time. During each time unit there is applied to the line either positive or negative battery as indicated in figure 1, the battery ordinarily being of 160 volts. No space occurs between consecutive characters. A measure of the speed of the circuit is the "dot frequency" or the "fundamental signaling frequency" of the circuit, which is the reciprocal of the time required for two consecutive units in the code character.

During its passage along the line the telegraph signal becomes rounded and the current becomes weakened. The practical working circuit speed is limited by the amount of weakening of the signal which can be tolerated in the presence of such extraneous currents as then exist. Any induced currents from external sources are of course superposed on the received telegraph current, and amounts of induction exceeding about six volts are sufficient to cause a measurable impairment of the telegraph.

In field measurements of telegraph transmission it is customary to examine the current sent and received, and the rate of change of the current between reversals. However, for analytical purposes it often is useful to regard the circuit as an a-c transmission system. While telegraph transmission would appear superficially to be wholly different in principle from that of power supply, there is only this basic difference, that while the power supply system need transmit one frequency only, the telegraph circuit must be capable of sending a band of frequencies the lower limit of which is zero frequency and the upper limit of which is somewhat above the dot frequency.

If in the telegraph transmitter a given combination of signals is set up and is

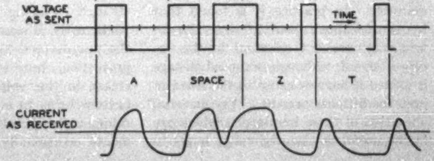

Figure 1. Typical signals in three-channel multiplex printing telegraph system

Paper 40-50, recommended by the AIEE committee on communication, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted October 20, 1939; made available for preprinting December 28, 1939; released for final publication March 13, 1940.

J. W. MILNOR is transmission engineer, The Western Union Telegraph Company, New York, N. Y.

repeated over and over, the combination may be analyzed by well-known methods into the sum of a number of sinusoidal waves of definite frequencies. In figure 2 are shown the frequencies contained in certain signal combinations when repeated again and again. Values above 200 cycles are not shown, although actually they continue with decreasing amplitude to infinite frequency.

Commercial telegraph traffic, of course, is made up of random reversals of voltage rather than of recurring signal combinations. In strictly random traffic the frequency spectrum is found to be continuous, that is, it contains substantially *all* frequencies from zero upwards, rather than certain discrete frequencies.

If the telegraph circuit were to transmit all frequencies without reduction in amplitude and in correct phase, the received signal would be identical to that sent. In practice the upper frequencies are reduced or removed in traversing the line, and the effect on received signal shape is to cause the rounding previously referred to. A certain degree of such rounding is not objectionable and may be desirable. In practice it is found that frequencies above about 1.6 times the dot frequency are not essential in the received signal, although some advantage is gained if harmonics up to the third or even the fifth are present. Any material alteration of those frequencies which are in the useful or essential range tends to cause distortion or mutilation of the received signals.

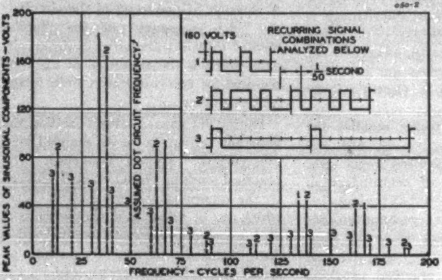

Figure 2. Examples of analyses of repeated telegraph signals into their sinusoidal components

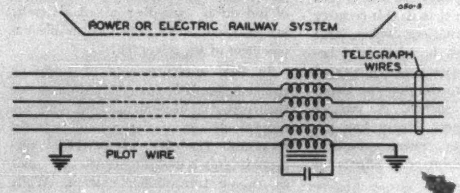

Figure 3. Multiwire neutralizing transformer

Devices for Separating Power Induced Voltages From Telegraph

Once extraneous voltages have been induced from a power system into telegraph, their removal is difficult only because of the need for minimizing any direct impairment to the telegraph. Equipment for removing the interference must not introduce any material added impedance into the telegraph nor remove any essential components of the telegraph currents, otherwise its objective is defeated. Among telegraph circuits carried along a common route there ordinarily is some tendency to induce currents known as "cross fire" into each other; the equipment for removing power interference must not increase such cross fire.

Interference of course can be removed by replacing the customary ground-return telegraph circuit by a metallic telegraph, using two line wires instead of one. Or a carrier telegraph may be substituted. Placing the wires in cable, particularly if armored, is effective for the purpose and also affords mechanical protection, but is expensive. An increase in the voltage of the telegraph battery helps to a small extent in overriding induced voltages. Such arrangements occasionally may be justified to reduce power interference, but hardly can be considered to be a general solution as a co-ordinative measure.

Devices for removal of induced power voltages are of two general classes. In the first a pilot wire set aside for the correction, is placed on the pole line carrying the telegraph wires and extends throughout the length of the exposure to power. The second class of devices depends upon tuning to remove the sinusoidal power current.

Mitigative Systems Including a Pilot Wire

The pilot wire is exposed to the same induced voltage as the telegraph wires. This is conducted by the pilot wire into suitable equipment which in turn applies to the telegraph wires a voltage to neutralize the interference.

NEUTRALIZING TRANSFORMER

Illustrated in figure 3, this is a relatively simple device which under suitable conditions is fairly effective. In one form it was used early by Professor C. F. Scott. All wires on the pole line may be corrected simultaneously, all transformer coils in the multiwire transformer being wound on the same iron core.

As at present developed the step-up ratio is only slightly above unity, and the inductance of the primary winding is tuned to the disturbing frequency. To prevent partial saturation of the core by currents in the telegraph wires, an air gap is included in the core. The correction of voltages up to 200 in an exposure 20 miles in length, has been obtained with a transformer weighing 500 pounds, in as many as 34 wires carried on the same pole line. The removal of power interference is nearly perfect unless limited by conditions such as local earth potentials at the grounding points, but the system tends to add cross fire between the various telegraph circuits.

As in all other correcting systems it is necessary to examine the direct effect of the transformer on the telegraph currents. The transformer adds impedance in each telegraph wire, but more important is the cross fire induced between

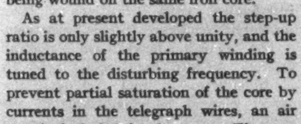

Figure 4. Neutralizing transformer for correction of two frequencies

the various wires. These effects may be controlled by holding to a low value the resistance of the primary circuit. That is, a mutual impedance exists between each pair of telegraph circuits, which may be considered to consist of an inductance shunted by the capacitor and by the primary circuit. The resistance of the latter including the wire and its earth connections should not exceed 40 ohms and preferably should be lower. To this end there have been used pilot wires as large as number 3 Brown and Sharpe gauge, with earth connections made of a dozen paralleling grounding pipes. The limitation in resistance obviously sets a limit on the length of exposure in which a multiwire neutralizing transformer can be used economically, where high-speed telegraph circuits operate.

If the telegraph circuits are worked at low speed, or if a separate pilot wire is provided for each telegraph circuit, the limitation as to length becomes less difficult. Individual line neutralizing transformers have been used in exposures up to 60 miles in length using a pilot wire of number 9 Brown and Sharpe gauge in a relatively low-speed telegraph circuit, for correction of 25-cycle interference.

The neutralizing transformer may be used for simultaneous correction of several frequencies. An arrangement in service for removing 25- and 75-cycle interference is shown in figure 4, and includes, in addition to the transformer, a second capacitor and an added reactor.

The above transformers were designed for use during normal working of the disturbing power or railway system. A unique application has been made in a five-mile exposure of an electrified railway to circuits of a burglar-alarm system, where frequent railway short circuits caused false alarms by induction. In this case the induction reached values over 100 volts which were interrupted in about one cycle through the operation of railway circuit breakers. A transformer was provided which could adjust itself sufficiently quickly to correct the transient voltage, by tuning to 25 and 50 cycles through the use of two coil-capacitor units shunting the primary coil, and was effective in neutralizing the abrupt severe surges of voltage.

NEUTRALIZING GENERATOR

The neutralizing generator formerly has been in service use but is now superseded by the system next to be described. It will be discussed briefly because of the light it throws on the general problem.

Various arrangements of this have been developed, of which one is shown in figure 5. A multiwire transformer is energized by means of an a-c generator, and counterbalances the induced voltages both in telegraph wires and in the pilot wire. Any residual voltage in the latter is rectified in a mechanical rectifier driven synchronously with the generator, and after amplification serves to correct the voltage of the generator and the speed of the driving motor until the correct compensation is effected.

The system is effective in correcting interference, but is sluggish in adjusting itself when changes occur in the induced voltage. All a-c components of the telegraph signals must flow through the generator armature, and in order to minimize the addition of impedance in the telegraph wires and the tendency to cause cross fire between them, the impedance of the armature must be held to a low value. The pilot wire may be of the wire size ordinarily used for telegraphy, and the system is practical for exposures much longer than is the multiwire neutralizing system previously described.

NEUTRALIZING AMPLIFYING SYSTEM

This system is probably the most valuable of those available. It has made it possible to maintain practically normal operation in over 260 telegraph wires which are exposed to interference at 25 cycles from the electrified zone of a large eastern railroad, where voltages approaching 200 volts are induced. The system is also in use elsewhere for correcting interference at 60 cycles.

The neutralizing amplifying system is illustrated in figures 6 and 7. As with systems previously described, a transformer serves to impress on each telegraph wire a voltage to counteract the disturbing voltage induced in line wires. In this case the transformer is energized by a vacuum-tube amplifier. The voltage induced in the pilot wire is also opposed by the voltage in one coil of the transformer, and the residual is impressed upon the amplifier. The ratio of the potentiometer is not the same as the turns ratio of the opposing coil with respect to the line coils. Through adjustment of each of these ratios it is possible to obtain a step-up action which provides neutralization approaching 97 per cent. Since the system is aperiodic, it is able to neutralize sudden surges of voltage such as caused by power-system short circuits, as well as continuous interference within the voltage limitations of the equipment.

The manner of providing for the passage of the useful telegraph currents is unique. It might appear that the arrangement would impress a high impedance upon the telegraph currents, and would tend to add cross fire between circuits. The circuit, however, is such that a current is caused to flow in the transformer coil in the output of the amplifier, which (corrected for turns ratio) is equal to the sum of the telegraph currents in all line coils, thus cancelling any flux in the transformer due to telegraph currents. If the current in the output coil departs from the amount to

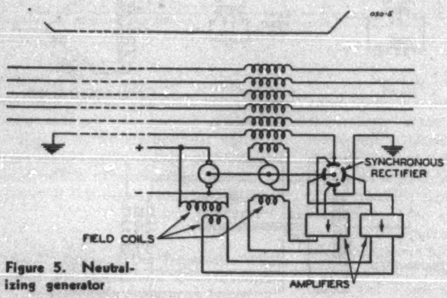

Figure 5. Neutralizing generator

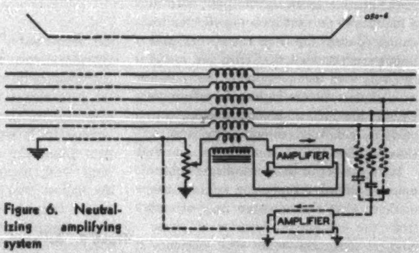

Figure 6. Neutralizing amplifying system

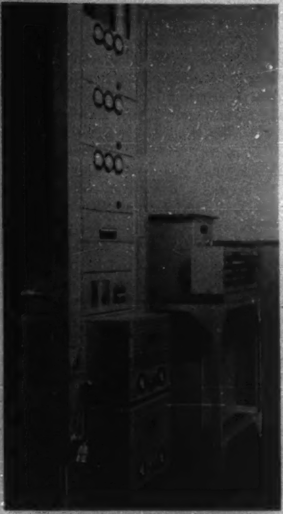

Figure 7. Neutralizing amplifying system for correction of 150 volts at 25 cycles in 60 telegraph wires

balance the telegraph currents, a residual voltage is immediately impressed upon the input of the amplifier tending to correct that condition.

A complication occurs in connection with the cross fire which normally occurs between telegraph wires carried on a given pole line. If the cross fire between all circuits including the pilot wire were equal, this system would also be effective in reducing the cross fire. Actually it is impracticable to locate the pilot wire in a manner to prevent its being affected by enhanced cross fire from a few wires, and unless compensated that cross fire would interfere with the operation of the system as a whole. Where high-speed telegraph circuits are present a correction for this crossfire condition is necessary and is shown in dotted lines in the figure.

With one set of the neutralizing equipment as shown, a limitation exists in the distance that the exposure may extend from the equipment, because of phase changes along the wire. The efficiency tends to decrease where the distance exceeds 20 miles in the case of 60-cycle interference, or where it exceeds 40 miles with 25-cycle interference. These distances are reduced if the telegraph wires are in cable. These limitations are removed by utilizing two sets of equipment, one at or beyond each end of the exposure, in which case the pilot wire may be 200 miles or more in length.

An arrangement somewhat similar in principle to the one illustrated was first shown by H. M. Trueblood of the Bell Telephone Laboratories. In its present form the system was developed here by W. D. Cannon.

Mitigative Systems Dependent Upon Tuning

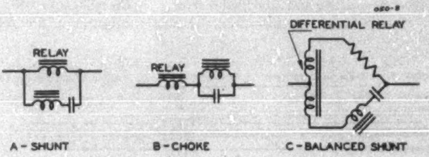
Many combinations of reactors and capacitors have been proposed with the view to reducing or removing extraneous sinusoidal currents by tuning. The expense of a pilot wire is thus avoided. The tuning removes those same frequencies from the useful telegraph currents and thus may impair the operation of the telegraph circuit by an amount dependent upon the relative frequency of the telegraph and the interfering frequencies, and upon the breadth of the tuning. A description of a small number of tuned devices will suffice to illustrate their practical value in mitigating interference.

Resonant Shunts and Resonant Chokes

A simple resonant shunt or choke, as shown in figures 8*A* and 8*B*, was introduced early for removal of interference. It may remove 95 per cent of the interference, but because of its coincident removal of useful telegraph currents it can be used only where the dot telegraph frequency is less than about half of the interfering frequency. This greatly restricts its use in modern systems of telegraphy. The effectiveness of the coil increases with its size; the above statements are based upon the use of an inductor weighing 20 pounds.

While simple resonant devices cannot be used for removal of 25- or 60-cycle interference from high-speed telegraph circuits, the resonant shunts are effective in such circuits where the interference results from power harmonics at 180 cycles. For application where conditions permit, the resonant shunt is placed in parallel with the working telegraph relay. The resonant choke is convenient for use in "way" telegraph circuits where a number of stations operate on the same line, since one choke may serve where several of the resonant shunts would be required.

Figure 8. Resonant devices for reducing interference

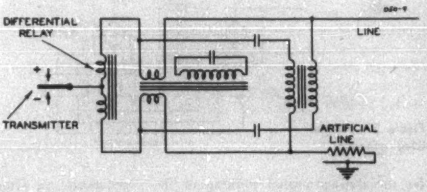


Balanced Double-Resonant Network

A balanced arrangement shown in figure 8*C* was proposed by E. Blakeney and R. E. Chetwood, which in theory may remove all of the interference. The resistor is adjusted to equal the a-c resistance of the coil and capacitor at resonance. Advantage may be taken of the arrangement to increase the value of the inductance and reduce the amount of capacitance, with the result that the impairment to the telegraph is much reduced.

That arrangement has been little used, but a development from the same principle is the balanced double-resonant network shown in figure 9. The theory of this is rather involved, but it may be considered that the a-c resistance of a double-resonant shunt is balanced against that of the resonant choke combination in a manner to remove nearly all interference. Partly through the circuit design and

Figure 9. Balanced double-resonant network



partly through an increase in the weight and effectiveness of the inductors, a much improved performance results. Each inductor is designed to offer the highest ratio of reactance-to-resistance obtainable within practicable size limits. The cores are of silicon steel and contain air gaps. This device is wholly practical, and with some moderate impairment of the telegraph currents it may be used where the telegraph dot frequency approaches nine-tenths of the interfering power frequency. Typical plots showing the efficiencies of various tuned devices in removing interference are shown in figure 10.

The effectiveness of the balanced double-resonant network is dependent upon the power frequency remaining nearly constant. Failures of the device in removing interference have occurred because of variations in the frequency of the disturbing power system.

Synchronous Selective Neutralizing System

The arrangement just described provides nearly the practical limit of sharpness of tuning which may be secured with direct use of coil-capacitor tuning. It is possible to obtain selectivity many times closer through the use of mechanical tuning, or by an arrangement which involves rectification, a delay network, and reconversion to alternating current. A system of this type is indicated in figure 11. With such tuning as plotted in figure 10, the amount removed from the telegraph frequency spectrum is so narrow, presuming that random telegraph traffic is transmitted, that the impairment to the telegraph signals is not serious, and the telegraph dot frequency is not limited to values below the disturbing frequency as was the case with other tuned devices.

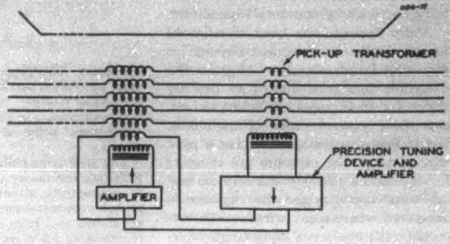


Figure 11. Synchronous selective neutralizing system

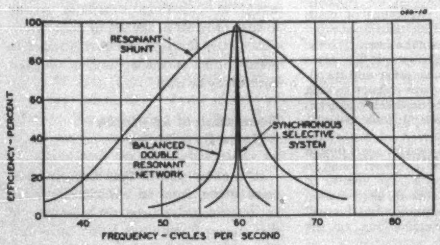

Figure 10. Efficiency of removal of sinusoidal currents by tuned devices

Table I. Telegraph Dot Frequencies Which Conflict With Operation of 60-Cycle Synchronous Selective Neutralizing System

Two-channel multiplex	25.0.....27.3.....33.3 37.5
Three-channel multiplex	37.5.....40.9.....45.0 50.0.....56.2
Four-channel multiplex	50.0.....54.6.....60.0 66.7.....75.0

The values listed include only those which occur within the customary range of operation of the stated equipment.

In practice a complication occurs because the telegraph signals are not wholly random. Certain characters, for example the letter "e", the space between words, etc., occur more frequently than others. When one multiplex channel is idle a blank is transmitted repeatedly, and at times circuit testing is done with a recurring set of characters. When telegraph signals containing such combinations are analyzed into their sinusoidal components (see section on telegraph theory) it is found that certain frequencies are more prominent than others and if one of those frequencies should nearly coincide with the interfering frequency there is impairment of signals and possible cross fire between circuits.

The values of those prominent frequencies have been computed by setting up combinations of signals likely to occur. For a two-channel multiplex it is found that the prominent frequencies are given by the formula $nF/5$, where F is the dot telegraph frequency and n takes all integer values from one to infinity. For the three-channel multiplex the formula is $2nF/15$, and in the four-channel multiplex it is $nF/10$. An exception is that frequencies of $2F$, $4F$, $6F$, etc., are not present, and frequencies near those values are of little importance.

There are, therefore, limitations upon the telegraph circuit speeds which can be worked to best advantage on a line where a synchronous selective neutralizing system is in use. A list of the telegraph dot frequencies to be avoided under these circumstances, as determined from the above formulas, where the interference is at 60 cycles, appears in table I.

Provision for passage of the useful telegraph currents is made in the same manner as in the neutralizing amplifying system previously described. The system is of course quite complex, and has the further disadvantage that a time interval of the order of 20 seconds is required for it to readjust itself for changes in amount of induced voltage, this sluggishness being a corollary of the extraordinarily sharp tuning. During that interval the interference remains partly uncorrected. Arrangements are incorporated for automatic adjustment of the frequency of the tuning to follow normal changes in the frequency of the power system. Interference from two unsynchronized power systems cannot be neutralized by a single set of this equipment.

Discussion and Conclusions

This discussion of methods for mitigating interference obviously has been quite one-sided, since due to limitations of space there has been no discussion of matters of design of the power system which may influence the interference, yet in many cases the best solution will call for some modification of the plans of the latter. Such matters are dealt with in various other publications. In general those features should receive consideration with every exposure, since the only procedure that can be justified is that in which the greatest total benefit is obtained with a minimum total expenditure.

Many devices have been investigated for application to telegraph circuits for removing interference, and of those the preceding has been limited to descriptions of a small number sufficient to indicate their general range of usefulness. Neutralizing systems embodying a pilot wire through the exposure are effective for all classes of telegraph service, and are most useful where the exposure is short and where many wires can be corrected with one set of equipment. Systems dependent upon tuning are frequently unsuitable because of a greater tendency to cause direct detrimental effects to the telegraph currents, but find application in some circumstances where pilot-wire methods would be uneconomical.

But because of the cost, of the added complexity in telegraph circuits already highly complex, and of the weakening of the useful signaling currents in some cases, there are often objections to the use of such correcting equipment in exposures causing moderate or small amounts of power induction. In each instance there is some minimum value of induced voltage below which the application of neutralizing devices is not justifiable. To the telegraph company the most serious type of exposure is that which creates small interference only—a conclusion which follows from the fact that such exposures are far more numerous than the more severe ones, and their damaging effect upon telegraph service is to some extent additive.

However, the application of neutralizing devices to the telegraph circuits is proper where conditions are such that the creation of an exposure causing material induced voltages is justifiable, and fortunately it is possible to state that through the use of different methods in different cases there have been few exposures which during normal conditions of the power system, are so severe individually as to effect any serious impairment to telegraph service.

Discussion

Discussion will be found in the 1940 annual Transactions volume and in the 1940 "Transactions Supplement" to Electrical Engineering.

Harmonic Theory of Noise in Induction Motors

WAYNE J. MORRILL
MEMBER AIEE

Synopsis: This paper presents a theory of noise generation particularly adapted to use with small motors. Since single-phase motors predominate in the small-motor field, a single-phase point of view has been employed.

The underlying philosophy of the paper is to reduce the theory to simplest terms and to concentrate attention upon the most probable sources of noise. While the results are shown as a large collection of numbers representing force waves the development steps of the theory are really simple and easily understood.

The resultant air-gap flux wave in an induction motor is the difference between the fundamental stator flux plus its harmonics and the fundamental rotor flux plus its harmonics. The difference between the two fundamental fluxes is usually less than the larger one and often less than either one but the harmonics, with few exceptions, are neither of the same velocity nor space order and, therefore, do not add or subtract from each other. It follows that the resultant flux wave has more harmonics of much greater per-unit amplitude than does either the stator or rotor flux wave alone. It is the interaction of two large harmonic flux waves of slightly different space order and traveling at high frequency with respect to each other that causes high-frequency magnetic-force waves of long space pitch which are effective in producing noise.

The theory has been used for some time in noise investigations and has been found to bear out test results on a large number of motors. It is hoped that its presentation will not only prove useful to others but will encourage further contributions to the understanding of noise.

THE present-day problems which confront the designers of electric motors have been to a considerable extent complicated by the necessity for producing motors of greater and greater quietness. Since the pressure of economics precludes the possibility of obtaining quietness by the introduction of massive structures, ways must be found to obtain desired levels of quietness with the same or lighter structures than those previously used.

There have been a number of papers on noise of electrical machinery which have undertaken to deal with the problem of producing quiet motors from a scientific designer point of view. Many of these papers have been unsatisfactory to those engineers who desire always to have a sound and rigorous theory against which to check data, form conclusions, and make predictions. Much of the work which has been presented on noise has been of an experimental nature and has been presented at least semiempirically. Other work has been presented which, experience indicates, appears to be based upon unnecessarily complicated conceptions.

It appears that a sound theory having a simple philosophy and starting from a few simple fundamental assumptions would at this time contribute greatly toward progress in the art of noise reduction. It is the purpose of this paper to present such a theory and to suggest how it may be used.

Generation of Air-Borne Noise By a Motor

It can be shown that the air-borne noise arising from an electric motor has as its principal source the vibration of the stator frame and yoke structure. The natural and correct assumption is that the magnetic forces set up in the air gap of the motor cause the frame structure to be distorted periodically with time and that the external surface of the frame in turn beats the air causing air-borne noise.

From the above conception of the mechanism of noise production it follows that a complete exposition of motor noise phenomena would include not only a method for determining the character, magnitude, and frequency of the disturbing forces set up in the air gap but also a means for determining the response of the stator structure to the disturbing forces.

Unfortunately, experience with tests on many motors indicates that there is sufficient variation in the response characteristics of apparently identical stator structures (assembled in complete motor)

Paper 40-13, recommended by the AIEE committee on electrical machinery, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted October 14, 1938; made available for preprinting December 21, 1939; released for final publication March 8, 1940.

Wayne J. Morrill is designing engineer, fractional-horsepower motors, General Electric Company, Fort Wayne, Ind.

Chart I. List of Largest Noise Force Waves

Stator Harmonic	Rotor Harmonic	Noise Frequency	Length of Magnetic Force Pole
N_f or M_f	R_f	$f[R(1-s)-1-s]$	$\frac{\lambda}{R-N}$ or $\frac{\lambda}{R-M}$
N_f or M_f	R_b	$f[R(1-s)+1-s]$	$\frac{\lambda}{R-N}$ or $\frac{\lambda}{R-M}$
N_f or M_f	T_f	$f[T(1-s)-1+s]$	$\frac{\lambda}{T-N}$ or $\frac{\lambda}{T-M}$
N_f or M_f	T_b	$f[T(1-s)-3+s]$	$\frac{\lambda}{T-N}$ or $\frac{\lambda}{T-M}$
N_b or M_b	R_f	$f[R(1-s)+1-s]$	$\frac{\lambda}{R-N}$ or $\frac{\lambda}{R-M}$
N_b or M_b	R_b	$f[R(1-s)+3-s]$	$\frac{\lambda}{R-N}$ or $\frac{\lambda}{R-M}$
N_b or M_b	T_f	$f[T(1-s)+1+s]$	$\frac{\lambda}{T-N}$ or $\frac{\lambda}{T-M}$
N_b or M_b	T_b	$f[T(1-s)-1+s]$	$\frac{\lambda}{T-N}$ or $\frac{\lambda}{T-M}$

to leave little hope that in the near future a reasonably exact expression for stator response can be presented. Calculations of stator response do have their place in a noise investigation but the results obtained thus far have been more qualitative than quantitative.

Because of the, as yet, unsatisfying results which have come from efforts to predetermine frame response characteristics no effort is being made in this paper to discuss this point. It is felt better to confine our attention to the subject of the magnetic forces causing noise and leave for the future the subject of the accurate calculation of the stator response. By presenting now that which is known for certain, effort on the part of others may be stimulated which will result in further advances in the art.

The theory will be based upon the assumption of an air gap having uniform length, constant permeance, and windings which are distributed in the usual way in finite numbers of slots. Such assumptions can be well justified in small electrical machinery where substantially closed slots are employed and where the problem of noise reaches its most acute form. In larger motors having open slots it is felt that many of the conclusions obtained by this theory will still be valuable because accompanying the use of open slots is the use of greatly increased air gaps which to a considerable extent minimize such phenomena as may arise from effects due exclusively to permeance variations. Another reason why the conclusions arrived at from this magnetomotive-force constant-permeance theory may be useful where the permeance is not really constant lies in the fact that analysis has shown that most of the phenomena arising from tooth and slot permeance variations are identical in every way with associated phenomena arising from harmonics of magnetomotive-force caused by windings placed in the same slot structure.

Development of Theory

It is well known that, in addition to the fundamental air-gap fluxes produced by the currents in the rotor and stator windings, harmonic fluxes are also produced. With symmetrical windings harmonic fluxes, with certain exceptions, may exist having a number of poles corresponding to any odd multiple of the fundamental number of poles. "Good" winding distributions generally limit the magnitude of harmonics of low order but with a given number of uniformly spaced slots nothing can be done about the magnitudes of the tooth harmonics because the "distribution factor" for the tooth harmonics is identical with that for the fundamental flux. With any given slot combination and fundamental number of poles the magnitudes and orders of the tooth harmonics are definitely determined in relation to the fundamental flux. There always exist an infinite series of tooth harmonics having magnitudes and orders as shown below.

$$\text{Order of harmonic} = \frac{\text{harmonic poles}}{\text{fundamental poles}} = 2Kn \pm 1 \quad (1)$$

$$\text{Amplitude of harmonic wave} = A_1 \frac{1}{2Kn \pm 1} \quad (2)$$

In the above equations

P_1 = fundamental number of poles
A_1 = amplitude of fundamental flux wave
n = number of teeth per pole
K = any integer

It will be noticed that the tooth harmonics go in pairs and that if there are nine teeth per pole in a 4-pole motor the largest pair of tooth harmonics are the 17th and 19th harmonics. These harmonics will have respectively 17 and 19 times as many poles as the fundamental flux and their amplitudes will be $^1/_{17}$ and $^1/_{19}$ that of the fundamental. The next largest harmonics will be the 35th and 37th and after these the 53d and 55th, etc.

There may be times when the second or third largest tooth harmonics will be important in producing noise but for the present only the largest tooth harmonics will be considered. The method outlined can be employed for any number of harmonics.

For the sake of clarity and to give a mental picture of the relative magnitudes involved, figure 1 has been prepared showing (dotted) the stair-step wave of flux produced by a four-pole winding in a 36-slot stator. Superposed is shown (solid) the fundamental component and the first pair of tooth harmonics corresponding to the stair-step wave. Both the harmonics as well as the fundamental wave of flux should be visualized as pulsating with time and, if it be assumed that figure 1 was drawn when the waves were maximum, the effect of the pulsation is exactly duplicated by dividing each pulsating wave into two oppositely gliding components each having half the amplitude shown.

If the forward and backward components be used there are now six stator flux waves to be considered. If the subscript "1" be always associated with the stator and the subscripts "N" and "M" are each associated with a member of and represent the order of the first pair of tooth harmonics, the forward and backward components of each wave may be expressed as shown below.

$$\left.\begin{aligned}
W_{1f} &= A_{1f} \cos\left[x\frac{\pi}{\lambda} - \omega t\right] \\
W_{1b} &= A_{1b} \cos\left[x\frac{\pi}{\lambda} + \omega t\right] \\
W_{1Nf} &= A_{Nf} \cos\left[Nx\frac{\pi}{\lambda} - \omega t\right] \\
W_{1Nb} &= A_{Nb} \cos\left[Nx\frac{\pi}{\lambda} + \omega t\right] \\
W_{1Mf} &= A_{Mf} \cos\left[Mx\frac{\pi}{\lambda} - \omega t\right] \\
W_{1Mb} &= A_{Mb} \cos\left[Mx\frac{\pi}{\lambda} + \omega t\right]
\end{aligned}\right\} \quad (3)$$

The forward component of fundamental stator flux acts on the rotor winding to produce a forward wave of rotor currents which in turn produces a forward wave of rotor fundamental flux moving at slip frequency with respect to the rotor. Associated with this forward fundamental

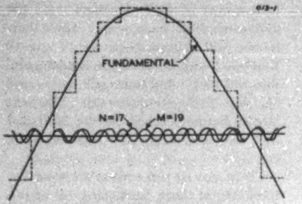

Figure 1. Fundamental and first tooth harmonics

flux is an infinite series of rotor tooth harmonic fluxes. Unlike the stator fluxes, the rotor fluxes, arising as they do from the action of a gliding wave of stator flux having constant magnitude, are not pulsating. They glide forward and backward on the rotor (forward with respect to the stator) with constant magnitude and at slip frequency with respect to the rotor.

The rotor tooth harmonics have poles and amplitudes as shown below:

$$\text{Order of rotor harmonic} = \frac{\text{harmonic poles}}{\text{fundamental poles}} = \pm\frac{2KB}{P_1}+1 \quad (4)$$

$$\text{Amplitude of rotor harmonics} = A_{2f}\left(\frac{1}{\pm\frac{2KB}{P_1}+1}\right) \quad (5)$$

In the above equations:

P_1 = fundamental number of poles
A_{2f} = amplitude of forward fundamental rotor wave
B = total number of rotor bars
K = any integer

When $K=0$ in equation 4, the first harmonic (the fundamental flux) is obtained and the positive sign indicates that the direction of motion of the fundamental flux wave with respect to the rotor is considered positive. A negative sign such as always occurs with the lesser-poled harmonic of each pair of tooth harmonics indicates that that harmonic is moving around the rotor in a direction opposite the motion of the fundamental flux. Throughout this discussion R indicates the negatively moving rotor tooth harmonic and the ratio of its poles to the poles of the fundamental. T will indicate the positively moving rotor harmonic and the ratio of its poles to those of the fundamental.

The backward component of fundamental stator flux is also responsible for producing a backward component of fundamental rotor flux gliding backward on the rotor at a frequency $(2-s)$ times the stator frequency. Corresponding tooth harmonics are also produced.

If only the fundamental and first pair of tooth harmonics be considered at this time there are in all six rotor fluxes. Neglecting the difference in time phase between stator and rotor currents, these six fluxes may be expressed with respect to the rotor as shown.

$$\left.\begin{aligned}
W_{2f} &= A_{2f}\cos\left[x_2\frac{\pi}{\lambda}-\omega st\right]\\
W_{2b} &= A_{2b}\cos\left[x_2\frac{\pi}{\lambda}+\omega(2-s)t\right]\\
W_{2Rf} &= A_{Rf}\cos\left[Rx_2\frac{\pi}{\lambda}+\omega st\right]\\
W_{2Tf} &= A_{Tf}\cos\left[Tx_2\frac{\pi}{\lambda}-\omega st\right]\\
W_{2Rb} &= A_{Rb}\cos\left[Rx_2\frac{\pi}{\lambda}-\omega(2-s)t\right]\\
W_{2Tb} &= A_{Tb}\cos\left[Tx_2\frac{\pi}{\lambda}+\omega(2-s)t\right]
\end{aligned}\right\}\quad(6)$$

With respect to the stator the rotor waves of (6) can be written:

$$\left.\begin{aligned}
W_{2f} &= A_{2f}\cos\left[x\frac{\pi}{\lambda}-\omega t\right]\\
W_{2b} &= A_{2b}\cos\left[x\frac{\pi}{\lambda}+\omega t\right]\\
W_{2Rf} &= A_{Rf}\cos\left[Rx\frac{\pi}{\lambda}-\omega[R(1-s)-s]t\right]\\
W_{2Tf} &= A_{Tf}\cos\left[Tx\frac{\pi}{\lambda}-\omega[T(1-s)+s]t\right]\\
W_{2Rb} &= A_{Rb}\cos\left[Rx\frac{\pi}{\lambda}-\omega[R(1-s)+2-s]t\right]\\
W_{2Tb} &= A_{Tb}\cos\left[Tx\frac{\pi}{\lambda}-\omega[T(1-s)-2+s]t\right]
\end{aligned}\right\}\quad(7)$$

The flux at every point in the air gap of the motor and at every instant of time is exactly representable as the sum of the fundamental fluxes and all the harmonic fluxes. Using those which have been considered we may write:

$$B_\delta = \left[\begin{aligned}&W_{1f}+W_{1b}+W_{1Nf}+W_{1Nb}+W_{1Mf}+\\&W_{1Mb}+W_{2f}+W_{2b}+W_{2Rf}+W_{2Rb}+\end{aligned}\right] W_{2Tf}+W_{2Tb} \quad (8)$$

The radial force density at any point in the gap due to B_δ is, according to Maxwell:

$$\frac{F}{A}=\frac{1}{72{,}130{,}000}B_\delta^2 \text{ pounds per square inch} \quad (9)$$

For purposes of noise study it is desirable to work with the components of the force density, which components are obtainable by the expansion of the square of the right member of (8). The expansion consists of the square of each term in (8) plus twice the product of each term with each other term. A complete expansion of even so few as the 12 terms chosen leads to 78 terms which are rather clumsy to handle by conventional means. In the appendix is given a simple shorthand means for performing the expansion and there has been prepared a multiplication table showing results for the case of a four-pole 36–48 combination motor.

At this time it is of interest to perform one of the multiplications in order to discuss the results obtained. In the case of the N forward stator tooth harmonic and the R forward rotor harmonic the product is:

$$\Delta F_{(Nf)(Rf)} = A_{Nf}A_{Rf}\cos\left[Nx\frac{\pi}{\lambda}-\omega t\right]\times \cos\left[Rx\frac{\pi}{\lambda}-\omega[R(1-s)-s]t\right] \quad (10)$$

$$\Delta F_{(Nf)(Rf)} = A_{Nf}A_{Rf}\times \left\{\cos\left[(R-N)x\frac{\pi}{\lambda}-\omega[R(1-s)-1-s]t\right]+ \cos\left[(R+N)x\frac{\pi}{\lambda}-\omega[R(1-s)+1-s]t\right]\right\} \quad (11)$$

It will be seen from (11) that the product of the two flux waves is representable as two force waves, the upper wave having a long wave length and the lower one having a very short wave length.

Chart II. No-Load Noise Forces for Four-Pole 36–48 Motor

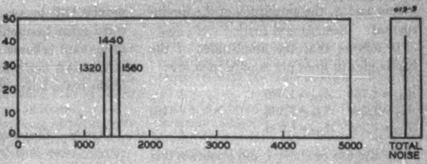

Figure 3. Noise spectrum taken on a four-pole (36–48) motor

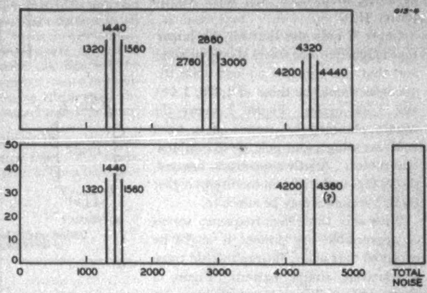

Figure 4

Top—Calculated noise-force spectrum on a four-pole (36–48) motor
Bottom—Noise spectrum taken on a four-pole (36–48) motor

In general, very short force waves will not be important because the stator will be very stiff to short-wave distortion. Long waves of force, however, will cause a relatively large response and therefore will be important in producing noise. The pitch of the long force wave is:

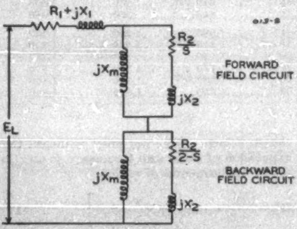

Figure 2. Equivalent circuit for a single-phase motor

$$\lambda_{(Nf)(Rf)} = \frac{\lambda}{R-N} \tag{12}$$

The frequency of this wave is:

$$f_{(Nf)(Rf)} = f[R(1-s)-1-s] \tag{13}$$

and this frequency is, of course, the frequency at which the air-borne noise will be emitted.

A study of the various products involved shows that those products most likely to be responsible for noise are the ones of long pitch produced by the multiplication of a stator harmonic with a rotor harmonic. There are 16 such products and they will be listed here for future reference (chart I). In appendix I a complete listing of the product terms is given but the simplifying assumption has been made that $s=0$. It may at times be desirable to have available the expression for noise frequency when $s \neq 0$.

It will be noted that the frequency does not change when the N_f stator harmonic is substituted for the M_f but the force wave length does.

Sample Force-Wave Calculation

A specific calculation will now be introduced to show how the force waves may be calculated for a particular motor.

Assumptions

Gap diameter	=3.5 inches
Stacking length	=2 inches
Stator slots	=36
Rotor slots	=48
Fundamental poles	=4
Maximum fundamental density	=30,000 lines per square inch
Maximum load current	=2 (no load current)

The order of the largest stator tooth harmonics may be calculated by means of equation 1.

$$\left.\begin{aligned} N &= 17 \\ M &= 19 \end{aligned}\right\} \tag{14}$$

The order of the largest rotor tooth harmonics may be calculated by means of (4).

$$\left.\begin{aligned} R &= 23 \\ T &= 25 \end{aligned}\right\} \tag{15}$$

At no load the forward field rotor currents are negligible (see figure 2) and the forward-field rotor tooth harmonics listed on chart I will be ineffective in producing noise. In the backward field, while the rotor and stator fundamental fluxes neutralize each other, as shown by the low voltage which exists across the backward field at no load, it will be assumed that because of poor distribution factor and spiral the harmonics exist practically undiminished.* On the basis of this assumption the stator harmonic fluxes and the backward-field rotor harmonic fluxes are subject to the same ampere turns as is the fundamental flux; consequently they will exist in their normal magnitudes (A_1/h) where h is the order of the harmonic and A_1 the amplitude of the fundamental. [See (2) and (5).]

---

* Note: If desired the rotor secondary characteristics to each stator harmonic can be carefully calculated and an exact determination of the diminution of the stator harmonic fluxes determined. The stator winding will have almost no diminishing effect on rotor harmonics.

It follows that the amplitudes of the harmonics in lines per square inch are:

$$\left.\begin{array}{ll} A_{17f}=1{,}765 & A_{19b}=1{,}580 \\ A_{19f}=1{,}580 & A_{23b}=1{,}305 \\ A_{17b}=1{,}765 & A_{25b}=1{,}200 \end{array}\right\} \quad (16)$$

By the use of chart I and equation 9 it is now possible to list maximum force densities, frequencies, and wave lengths (chart II).

Chart II indicates that all the important magnetic-force waves should be small and that the principal no-load noise frequencies should be those of 1,320, 1,440, and 1,560 cycles. Figure 3 shows the results obtained by means of a noise analyzer using a four-pole 36–48 combination motor. Another spectrum, figure 4, shows that under certain conditions higher tooth harmonics may be effective.

With only three high-frequency waves of appreciable size present it might be expected that an oscillograph would trace a relatively simple pattern. Figure 5 shows two oscillographs which bear out the idea of pattern simplicity. These were taken using a velocity pickup and a high amplification to the oscillograph.

Figure 6 gives noise spectrums taken on four-pole motors of other slot combinations. These may be compared with chart VII.

The force waves under load will be larger since, as indicated under "assumptions", the maximum load current is twice the no-load current, all the stator harmonics and backward rotor harmonics will be twice as large. The forward rotor harmonics which do not exist at no load become almost as large as the others and not only are the magnitudes of the noise forces increased but the character of it is changed. (See the discussion of no-load versus load noise in appendix I.)

Appendix I

In the calculation of magnetic force waves in the course of actual design work it is desirable to have a systematic method of work. This section of this paper describes such a method.

If time-phase relations are not important the equation for a magnetic flux wave as given in equations 3 and 7 expresses for us the following:

Amplitude
Order (pitch, distribution)
Frequency
Direction

If we deal with tooth harmonics the relation expressed in (2) and (5) is valuable in connecting amplitude with pitch so that if the pitch is known the amplitude is known. In such event only the pitch need be defined. If frequency be given a sign the symbol for frequency may be used to express both frequency and direction.

Chart VI. High-Frequency Noise Terms, 36–48 Slot Combination

ROTOR TOOTH HARMONICS	STATOR TOOTH HARMONICS 17 +1	17 -1	19 +1	19 -1	
23	6	6	4	4	a
+25	24	26	24	26	
23	6	6	4	4	b
+23	22	24	22	24	
25	8	8	6	6	c
+23	22	24	22	24	
25	8	8	6	6	d
+25	24	26	24	26	

If we make these simplifications in our present case we may express any traveling wave by two numbers.* It is convenient to make these numbers "per unit" numbers as shown below. (By "per unit" is meant the expression of order and frequency as a ratio to the fundamental of each.)

$$W_a=\boxed{\frac{18}{-2}}=\cos\left[18\times\frac{\pi}{\lambda}+2\omega t\right] \qquad (17)$$

If the upper number in the box be the order of the flux harmonic (the number of poles of the wave per fundamental pole) and the lower number the ratio of the harmonic frequency to the fundamental frequency, the wave W_a is seen to have 18 times the fundamental number of poles and to be moving backward (because of the minus sign) at twice fundamental frequency.

The conventional expression for the wave is also given in (17) and it can be seen that the numerical coefficients of the conventional expression are used in the new nomen-

---

*NOTE: It is obvious that, if desired, a four-number system could be similarly set up representing phase relation, order, magnitude, and frequency-direction. For our present purpose the simplification is desirable.

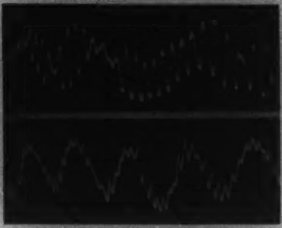

Figure 5. Cathode-ray oscillograms of stator-yoke vibration, 36–48 combination

clature except that the sign of the frequency term is reversed.

If it is desired to multiply two waves using the convention it is merely necessary to add and substract numbers of the same significance. For example:

$$W_b=\begin{vmatrix}\frac{14}{4}\end{vmatrix}=\cos\left[14\times\frac{\pi}{\lambda}-4\omega t\right] \qquad (18)$$

$$W_a\times W_b=\left[\begin{array}{l}\frac{1}{2}\cos\left[32\times\frac{\pi}{\lambda}-2\omega t\right]+\\ \qquad\frac{1}{2}\cos\left[4\times\frac{\pi}{\lambda}+6\omega t\right]\end{array}\right] \qquad (19)$$

$$\underset{b}{\begin{vmatrix}\frac{14}{4}\end{vmatrix}}\times\underset{a}{\begin{vmatrix}\frac{18}{-2}\end{vmatrix}}=\underset{c}{\begin{vmatrix}\frac{32}{2}\end{vmatrix}}+\underset{d}{\begin{vmatrix}\frac{4}{-6}\end{vmatrix}}=\underset{e}{\left|\begin{array}{c|c}32&4\\\hline 2&-6\end{array}\right|} \qquad (20)$$

Chart VIII. Rotor Subharmonics

		+17	+19	+17	+19
	37	14	14	6	6
		+17.5	+19.5	+17.5	+19.5
	38	16	16	8	8
		+18	+20	+18	+20
	39	18	18	10	10
		+18.5	+20.5	+18.5	+20.5
	40	20	20	12	12
		+19	+21	+19	+21
36	40	12	12	4	4
		+19	+21	+19	+21
	44	20	20	12	12
		+21	+23	+21	+23
	48	28	28	20	20
		+23	+25	+23	+25

In equation 20 a horizontal addition is made to obtain *c* from *a* and *b*. A horizontal subtraction is made (in the direction to make the upper figure positive) to obtain *d*. The two waves are written together as at *e*.

If the two waves W_a and W_b are flux waves their product according to previous discussion is a pair of moving waves of force tending to bend the stator yoke into as many nodes as there are waves of force.

The present resultant force waves are seen to have 32 poles and 4 poles and to be moving respectively at twice fundamental frequency forward and at six times fundamental frequency backward. It will be noted that the numerical coefficient $^1/_2$ is dropped for simplicity in view of its existence in all similar product terms. A further simplification will be made for our present purpose in that after multiplication the sign will be dropped from the frequency terms since direction of rotation has no effect upon airborne noise in which we are primarily interested.

It was shown previously that a complete expression for the force waves of a motor would multiply each term of both the stator and rotor Fourier series flux expression by itself and by each other term to form a second-order series of force waves. A multiplication form has been prepared and the operations performed for a 36–48-slot four-pole combination assuming no-load operation (chart III).

Inspection of the chart will show that when stator waves act together only "0" and "2" frequencies (0 and 120 cycles) exist. It is also apparent that when rotor waves act together high-frequency terms are produced (about 3,000 cycles) but the pitches of the waves are so short that it is extremely doubtful whether the resultant stator distortion could be detected.

All of the waves found in "*E*" and "*F*" will be found in "*A*" and "*B*" respectively and "*D*" will be found to be a replica of "*B*". Attention may therefore be concentrated upon section "*B*" of the chart when high-pitch noise is of interest.

If waves of extremely short pitch be discarded as being relatively ineffective we find ourselves with the same waves given in chart VI.

It is of interest to note that the four terms laterally adjacent to "*b*" and "*d*" result from forward-field rotor current and are, therefore, absent at no load and large under load. Terms adjacent to "*a*" and "*c*," however, are the result of backward-field rotor current and are large at no load as well as under load. The results of the analysis are statistically tabulated below in relation to the number of poles of force and the frequencies produced.

16 Poles	24 Poles	32 Poles
No-load noise forces (cycles)		
1,440	1,320	1,320
1,560	1,440	1,440
	1,440	
	1,560	
Additional-load noise forces (cycles)		
1,320	1,320	1,440
1,440	1,440	1,560
	1,440	
	1,560	

If motor noise is measured at no load it would be expected that the 1,440-cycle and 1,560-cycle noises would predominate since the stator is much stiffer to 24-node and 32-node bending than to 16-node bending. Under load the 1,320-cycle noise should become pronounced, though, due to slip, it will be somewhat displaced in frequency.

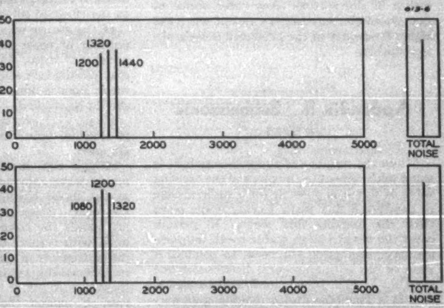
All no-load noises should be reduced practically to zero by polyphase operation or the use of a proper capacitor. The introduction of a balancing capacitor (effective only under load) should be accompanied not only by a reduction in noise level but by the elimination of the highest of the three tooth frequencies, causing a change of about 120 cycles in the mean pitch of the high-frequency noise. Two-phase operation should show this clearly.

Chart VII has been prepared giving principal magnetic-force waves for all the possible slot combinations for a satisfactory re-

Figure 6

Top—Noise spectrum taken on a four-pole (36–44) motor

Bottom—Noise spectrum taken on a four-pole (32–40) motor



frigeration-machine motor assuming both 32- and 36-slot stators.

It is of special interest to notice that whenever force waves of zero poles occur there exist "geared" waves of the same number of poles on the rotor and stator. The existence of such waves is accompanied by standstill locking and high-speed rotating subharmonic waves of fundamental distribution and high-frequency tooth-harmonic interference. (Discussed briefly later.)

A two-pole magnetic force tries to displace the entire rotor thus producing shaft vibration, a four-pole force tries to distort the stator yoke into the form of an ellipse, etc. It is to be assumed that, other things being equal, a magnetic force of many poles is to be preferred to one of few poles; because of the greater effective yoke stiffness when the wave length is short. Any force wave having less than eight poles is likely to be bad for noise.

Conclusions

It must be concluded that when a 32-slot stator is used the rotor is limited to 36 slots or 40 slots or more. If 36 slots are used it is questionable whether the locking and high-frequency interference (torque) noises can be kept from becoming a nuisance; spiral might control them. Above 40 slots there seems little reason to confine the slot combination to even slots if advantage is to be obtained by going to an odd number.

With a 36-slot stator the rotor possibilities are 28, 32, 40, 44, and higher. The remarks concerning the 36-slot rotor with a 32-slot stator apply to the 32- and 40-slot rotors with a 36-slot stator. Any rotor above 44 slots should be satisfactory except when the higher frequency of the produced noise is objectionable.

Appendix II. Subharmonic Waves

When the number of squirrel-cage bars is small with respect to the pitch of the exciting wave of flux it is possible for a squirrel cage to produce a flux wave having fewer poles than the exciting flux wave. In certain cases the always large stator-tooth harmonics may react upon the rotor to produce a wave of flux of fundamental distribution but rotating at such speeds as 70,000 to 80,000 rpm in a four-pole motor operating at normal 1,725 rpm speed. Such subharmonic waves become very important in the noise of a motor and must be taken into account. The procedure after determining the flux waves present is exactly as already described except that the subharmonic waves are included in the calculation along with the fundamental and tooth-harmonic waves.

Determination of Subharmonic Waves

Subharmonic waves may be determined as Chapman outlined in his book on induction motors by use of the equations:

$$S=\frac{2BK}{P_1}+h=\text{order and direction of subharmonic (direction referred to direction of } h \text{ with respect to rotor)} \quad (21)$$

$$f_s=\pm 1-\frac{2BK}{P_1}=\text{stator referred frequency in per-unit of fundamental frequency (single-phase stator)} \quad (22)$$

In the above equations:

B = total number of rotor bars
K = any positive or negative integer ($K=-1$ usually most important)
P_1 = number of fundamental poles
h = order of a stator harmonic (use plus sign always)

The magnitude of a subharmonic depends upon the rotor impedance as well as the linkage of the rotor and the stator in so far as the generating stator harmonic is concerned. If the stator harmonic is of short pitch, as are most tooth harmonics, a slight amount of spiral greatly reduces the mutual and reduces the subharmonic. Even without spiral the amplitude will usually be found to be less than $A_1(1/h)^2$. Since the calculation of subharmonic magnitudes is somewhat involved it is felt that an outline of the method is not warranted here. The intent of these remarks is merely to call attention to the effect of subharmonics.

If the stator winding is "good" and the number of rotor slots is greater than the number of stator slots by $2P$, subharmonics may usually be neglected. If the number of rotor slots is less than this subharmonics should be studied.

Chart VIII lists subharmonics for 32- and 36-slot four-pole stators when various rotors are used.

A plus sign in (21) indicates a subharmonic wave moving in the same direction as the stator harmonic, h, with respect to the rotor. Since at normal forward operating speeds the rotor is always moving forward with respect to any stator harmonic, the movement of the stator harmonic with respect to the rotor is backward. Under these conditions, if the sign of (21) is negative, it means that the subharmonic is moving in the opposite or forward direction with respect to the rotor and, of course, forward also with respect to the stator. Since a plus sign for a frequency number in chart VIII indicates a wave moving forward with respect to the stator, chart VIII would therefore have a positive frequency number when (21) is negative.

Nomenclature

A_1 = amplitude of fundamental stator flux wave
A_{1f} = amplitude of fundamental rotor forward wave
A_{NF} = amplitude of the N forward tooth harmonic
B = total number of rotor bars
B_s = total density in the air gap at the point x
f = frequency of primary excitation
K = any integer
n = number of stator slots per pole
N = largest stator-tooth harmonic
M = second largest stator-tooth harmonic
P_1 = fundamental number of poles
R = largest (least poled) rotor-tooth harmonic
s = per unit slip
T = second largest rotor-tooth harmonic
x = distance in inches measured peripherally around the air-gap surface
ΔF = force density (pounds per square inch)
λ = fundamental pole pitch (inches)

Current Transformers and Relays for High-Speed Differential Protection, With Particular Reference to Offset Transient Currents

E. C. WENTZ
ASSOCIATE AIEE

W. K. SONNEMANN
ASSOCIATE AIEE

Synopsis: Up to the present time, the only data generally available to protection engineers for determining the performance of current transformers have been the ratio and phase-angle curves of the current transformers in question. More detailed analysis of important high-speed differential protection problems has shown that these data are hopelessly inadequate for the purpose of determining the performance of current transformers during the starting period when the current wave may be fully offset. If the time constant for decay of the d-c component exceeds 0.05 second, large errors of transformation may be expected if standard current transformers are used. While it is possible to make special designs that will not saturate because of the d-c component in the current,[1] such designs are usually considerably oversize and expensive. Furthermore, space requirements and economy sometimes dictate that current transformers already installed be used if at all possible, even though it is known that their performance will be far from perfect. The problem then becomes one of determining the actual performance of existing current transformers, so that a suitable relay scheme may be chosen. It is the purpose of this paper to discuss the solution of this problem, and to present approximate methods of calculation not hitherto available. Attention is also given to the proper interpretation of the calculations with respect to relay operations, together with supporting test results.

THE PROBLEM of differential protection of generating-station busses is one which almost invariably requires calculation of current-transformer performance for asymmetrical currents, because of the long time constant of the generators. Figure 1 shows schematically a six-circuit bus protected by a simple overcurrent relay. The principle of differential protection indicates that, for an external fault at X, the current, i_1 through the relay should be zero. This is based upon the assumption that all the current transformers involved will perform perfectly. Inequalities are apparent at once, however, since it is seen that the transformer in circuit F_6 carries the total fault current, whereas the others each carry only a fraction of the total. The d-c component in the primary current, particularly troublesome when large generators are near the fault, aggravates the inequalities much more severely than is immediately obvious. For example, when conditions are severe, instantaneous peak values of i_1 may be of the order of 100 amperes when the symmetrical component of the total fault current is 100 amperes rms in terms of the secondary circuit.

The false differential current, i_1, which may exist when an external fault occurs at point X, is equal to the difference between the sum of the magnetizing currents of all the current transformers carrying current into the bus, and the magnetizing current of the current transformer carrying the total fault current away from the bus. (This can be derived from figure 1 by expressing each of the secondary currents in terms of their respective primary currents less the magnetizing currents of their respective current transformers, and solving for i_1, remembering that the sum of the currents entering the bus is zero for an external fault.) This forms the explanation for the inadequacy of ratio curves for this type of problem. It diverts the interest of the protection engineer at once from the question, "What will the secondary current be?" to the question, "What will the magnetizing current be?"

The authors have found that many protection engineers tend to underestimate the relative saturating quality of the d-c component of the asymmetrical current. Some have felt that, given a definite maximum instantaneous peak value for an asymmetrical current, it was only necessary to provide a current transformer whose performance would be satisfactory on symmetrical currents having the same peak values. This is definitely not true. For these reasons, the authors believe that the discussion immediately following is in order prior to the detailed mathematical treatment. This discussion is intended to convey a conception of the mechanics of d-c saturation in a form kept as graphical as possible.

The Mechanics of Saturation

A convenient way to analyze the performance of the current transformer of figure 2A is by means of the equivalent diagram as shown in figure 2B. With a given value of primary current, i, the values of primary-winding resistance and leakage reactance are of no consequence, hence these values are not indicated in the final diagram for analysis (figure 3). Also, for convenience, the secondary-winding resistance and leakage reactance are lumped with the burden and shown as R_2 and L_2. The mutual inductance between primary and secondary windings is shown by L_1, through which flows the magnetizing current, as indicated by i_1. It is possible to provide for the core loss current by including a suitable resistance in this branch, but this refinement is not necessary to provide sufficient accuracy for the problem at hand. This diagram is usable on the basis that the currents are expressed in terms of per cent of full-load current. Further, the diagram is usable

in that, electrically, it satisfies the requirement that the primary current minus the magnetizing current must equal the secondary current. The physical significance of the current, i_1, flowing through the mutual inductance, L_1, of figure 3, is that it represents in the equivalent diagram the vector difference between the primary and secondary currents in the actual transformer.

Figure 4. Leakage flux in different types of current transformers

Inspection of figure 3 will show that the mutual impedance, L_1, must be kept high with respect to the burden impedance, if good current-transformer performance is to be expected. If the symmetrical current only is considered, standard current transformers are usually adequate. Actual asymmetry of the fault current requires consideration of a new and very important factor. The d-c component of the primary current must also divide between the parallel branches of figure 3. Since, to all practical purposes, there is very little impedance to direct current in the magnetizing branch, L_1, of the parallel circuit, the flow of direct current in this branch is retarded only by the inductive voltage generated by the time rate of change of the direct current, as it builds up in this circuit. The voltage which must be generated is determined by the voltage drop across the burden, R_2 and L_2, caused by the d-c component flowing through it. If the d-c time constant is long, this direct voltage must be maintained for a relatively long time, and it can only be done by a continuously increasing current through L_1 at a relatively high time rate of change. This must be done in one direction only, without the advantage of positive and negative half-cycles characteristic of alternating current. This means that the knee of the saturation curve for the inductance, L_1, may be reached within a few cycles, or within a fraction of a cycle in severe cases. When the iron core saturates, the effective value of the inductance, L_1, decreases to a fraction of the normal value. When this occurs, the ability of the mutual inductance to retard the flow of direct current through it collapses, so that practically all of the d-c component goes through L_1. This condition will continue until the d-c component has subsided, after which the transformer can again perform with its normal a-c characteristics. It is of interest and importance to note that during the time that the magnetizing branch, L_1, remains severely saturated by direct current, it also offers much less impedance to the flow of alternating current; consequently, it is to be expected that the percentage of the a-c component which is transmitted to the secondary will be materially less. These conclusions are borne out by oscillographic records which show that, when a current transformer is failing to reproduce faithfully the d-c component in the secondary, it is also breaking down in a-c ratio, even though its performance may be quite accurate on the same value of symmetrical current.

Derivation of Formulas

Mathematical analysis of the current-transformer performance is based on the same equivalent circuit, shown in figure 3, and in fact, has already been worked out by Marshall and Langguth.[1] Their paper gives rules for keeping the flux density below the saturation value and for calculating performance, provided the transformer does not saturate, but, of course, cannot be used to indicate performance in cases where there simply is not room for the resulting design, or where existing transformers must somehow be used. The following analysis will be devoted to methods for calculating the performance, after saturation is reached. Important savings in space, as well as in weight and expense, may result if the analysis shows that current transformers which are far from perfect may still be adequate.

GENERAL CONSIDERATIONS

Returning to figure 2*B*, it must be recognized that although the sum of the leakage reactances, X_p and X_s, may be nearly constant and represent definite flux linkages, the effective division between X_p and X_s is different for every load condition, and they are individually practically impossible to determine.

Most problems deal with the "through" or "bar" type of current transformer, which can be so designed that the leakage flux which enters the core is negligible, and the following theory has, therefore, been worked out on the basis that the secondary leakage reactance is zero. The theory cannot be indiscriminately applied to wound-type transformers nor to through-type transformers with coils only on two legs of the core (see figure 4) without preliminary investigation of the relative amount of leakage flux.

The theory described assumes that the reactance of the burden is also zero. The justification for this is difficult to establish rigorously, but it can be readily estimated that once the d-c component of current is established (as it is during the first half-cycle) the inductance in the burden will present no obstacle to maintaining it, while the resistance in the burden acts against the direct current with a more or less continuous counter (*IR*) voltage. The

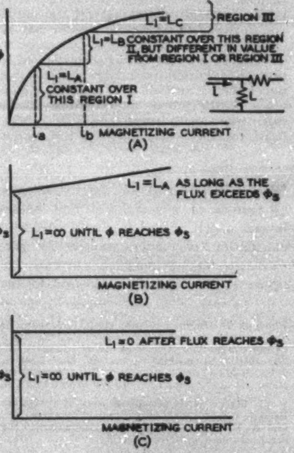

Figure 5. Approximations of the saturation curve

The true saturation curve may be approached as closely as may be desired theory has been worked out and calculations made with inductance in the burden, and it has been found that it makes very little practical difference in the result if the inductance is neglected, at least for burden power factors of 80 per cent or more. Tests confirm this.

The value of the assumption that $L_2=0$ is that the numerical work of calculation is approximately halved. After an example has been worked out, the importance of this becomes obvious. In the short-cut method to be described later, the secondary inductance may be included, but it can be shown that it can be neglected with negligible error.

The final assumption is that the equivalent resistance of the magnetizing branch of the network is zero. Correctness of this assumption is more difficult to prove, but actual results indicate that it is always practically true.

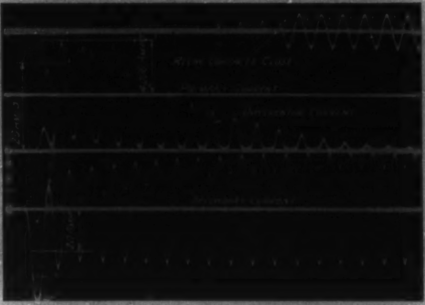

Figure 6A. Oscillogram showing that nonsaturating current transformer (primary current) balanced against current transformer that saturates (secondary current) gives a false differential current

Primary current, 4,000 amperes rms, $T=0.075$, ratio 1,000/5, test current transformer core area 1.69 square inches, secondary resistance 1.05 ohms

FUNDAMENTAL EQUATIONS

The equivalent network to be analyzed is thus very simple, figure 3, and may be analyzed exactly as Marshall and Langguth have previously done, except that $L_2=0$.

The equation for the difference current will be the same as given by Marshall and Langguth (equation 15, corrected) in their paper, except to neglect L_2.

$$i_1=\frac{1}{R_2T_1}\epsilon^{-t/T_1}\int R_2i\epsilon^{t/T_1}\,dt+C\epsilon^{-t/T_1} \qquad (1)$$

where $T_1=L_1/R_2$.

If the circuit is closed at the moment to get a fully offset primary current:

$$i=I\,(\cos\omega t-\epsilon^{-t/T}) \qquad (2)$$

Substituting for i and performing the indicated integration gives:

$$i_1=I\left[\frac{\cos\,(\omega t-\Delta)}{\sqrt{1+(\omega T_1)^2}}-\frac{T}{T-T_1}\epsilon^{-t/T}\right]+C_1\epsilon^{-t/T_1} \qquad (3)$$

$$\Delta=\tan^{-1}\,\omega T_1$$

$$T_1=\frac{L_1}{R_2}$$

This equation is perfectly general, and is the one on which the calculation of exciting current will be based. Its limitation in actual use is that L_1 (and T_1) are assumed to be constant; in the actual problem the solution must be carried out into the region of saturation, and L_1 (and T_1) will vary.

Step-by-Step Solution

THREE-ZONE SATURATION CURVE

Any saturation curve can be represented as closely as may be desired by a number of straight lines. This makes it possible to consider the inductance constant in a given region, as in figure 5*A*. With such an approximate curve, the magnetizing current may be calculated by means of equation 3. The procedure is to begin at time, $t=0$, setting $L_1=L_A$, $i_1=0$, evaluate C_1, and calculate i_1 at various values of t. It must be remembered that each time that i_1 enters a new region, figure 5*A*, the value of L_1 must be changed correspondingly, and a new value of C_1 obtained. This procedure gives good results, but is very laborious, and quite impractical for most problems. Further simplification is desirable.

TWO-ZONE SATURATION CURVE

It will usually be found that the exciting current will be negligible in its effect on the differential relay until the upper region of the saturation curve is reached. This justifies the assumption of a more simple shape of the saturation curve, as in figure 5*B*. The advantage of this shape is that L_1 is infinite until the "saturation" flux is reached, and the boundary conditions at the same time, t_1, at which ϕ_s is reached are: $t=t_1$, $i_1=0$. Returning to equation 5 in the paper by Marshall and Langguth, the flux will be (letting $L_2=0$ and writing I_s for N_pI_p/N_s)

$$\phi=\frac{10^8I_s}{N_s}\left[\frac{R_2\sin\omega t}{\omega}+R_2T\epsilon^{-t/T}\right]+C \qquad (4)$$

The procedure of calculation will be:

1. Calculate the flux variation beginning at time, $t=0$, $\phi=0$. Evaluate C accordingly, and calculate ϕ at several intervals of time, t, as necessary to determine the time, t_1, at which the flux will reach the "saturation" value, ϕ_s.
2. The new boundary conditions to be used now in equation 3 will be $t=t_1$, $i_1=0$. Evaluate C_1 and calculate i_1 at suitable intervals of time. Inspection of the equation shows that i_1 may be maintained at a positive value for a considerable length of time if the values of t, C_1, and T are suitable.
3. However, i_1 will eventually pass through zero. When it does at time, $t=t_2$, we must return to the equation 4 for ϕ and substitute the boundary conditions, $t=t_2$, $\phi=\phi_s$. The variation of ϕ must then be calculated. Usually, it will return to the "saturation" value of ϕ_s within a fraction of a cycle, say at time, t_3.
4. At time, t_3, $i_1=0$, determine a new value of C_1 and continue calculation of i_1.

This procedure might appear to be fully as difficult as that of the first method. Actually, it is much easier, and usually gives results which are not appreciably different.

If circuit constants are such that the exciting current (paragraph 2 above), is maintained at a positive value for a number of cycles, equation 3 shows that this exciting current is composed of a sinusoidal component with two superimposed d-c components. Unless the top of the saturation curve has an appreciable curvature, there will be few harmonic components in the exciting current. The variation of flux may occur over a relatively short zone along the top of the saturation curve, which may be nearly straight. Of course, the actual flux variation is always along a superimposed hysteresis loop, and the equivalent degree of curvature with the resulting harmonic components cannot be practically determined on any exact basis. However, tests show that the actual differential current may often be very nearly sinusoidal.

FLAT-TOP SATURATION CURVE

A still more simple method is to assume that the saturation curve has a flat

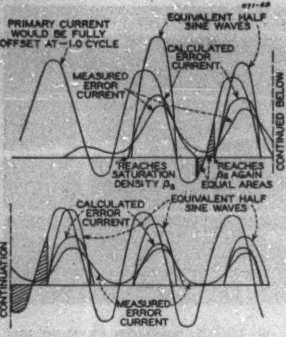

Figure 6B. Check of calculated error current against measured error current of figure 6A

The lower section of the figure is a continuation of the upper section. The "calculated error current" was calculated by the step-by-step method, equation 3 and sloped-top saturation curve, and the "equivalent half sine waves" were calculated using equation 12

Constants for calculated error current: $I=28.3$, $T=0.075$ ωL_1 corresponding to slope of top of saturation curve$=1.37$, $R_2=1.05$, $A=1.69$ square inches

top, so that L_1 will be zero after saturation (figure 5*C*) and the current equation will become:

$$i_1=I(\cos \omega t-\epsilon^{-t/T})$$

This is the same as the expression for the primary current, and shows, as would be expected, that if the saturation is complete at density, ϕ_s, there is no further reproduction of current in the secondary circuit until the time during the cycle when the primary current again passes through zero. At this time, the flux will tend to decrease below ϕ_s and the primary current will, thereafter, be perfectly reproduced until the flux once more increases to ϕ_s.

Figure 6*B* shows the exciting current as measured, and as calculated according to the sloped-top, and the flat-top saturation curve, compared with test values, for a given example. It can be seen that the calculated values according to both methods are in fair agreement with the test values.

Approximate Formulas

All these methods involve a great deal of numerical work. They are entirely too difficult for use in making the large number of preliminary estimates of performance which must be made during the study of a system of protection for a given bus layout. A still more simple solution is based on some rather bold assumptions. The justification of these assumptions will be shown to be two-fold:

1. The assumptions will be such that the final result will be pessimistic.
2. The results will agree sufficiently well with actual tests to be generally useful.

Returning to figure 6*B* it will be seen that the measured exciting current exhibits the following characteristics:

1. The area under the test current wave is very nearly the same as the area under the calculated current wave.
2. The exciting current wave form is approximately that of a half-wave rectified current.

These characteristics are shown in a large number of oscillograms, some of which are shown in figures 6*A*, 10*A*, and 10*B*.

From these considerations we will make the following assumptions:

1. The exciting current can be calculated and dealt with on the basis that it will always be a half sine wave.
2. The magnitude of it can be calculated on the basis that the area under the half wave will equal the area under the exciting current wave calculated by the previously described method.

The meaning, and the advantage of assumption 2 will be apparent from the consideration that the area of the exciting current wave can be determined fairly simply from the fundamental equation:

$$N\frac{d\phi}{dt}10^{-8}=R_2i_2$$

$$N\phi 10^{-8}=10^{-8}\int N d\phi=R_2\int i_2 dt \qquad (5)^*$$

and the consideration that ϕ will be at the saturation value at both beginning and end of a cycle, and that if the integration is from beginning to end, $N\phi$ must, therefore, be zero. The equation then becomes simply:

$$R_2\int_{t=(n+1)T_0}^{t=nT_0} i_2 dt=0 \qquad T_0=\frac{1}{f} \qquad (6)$$

However, the actual integral of an asymmetrical primary current over a cycle is obviously not zero. The meaning of this is that the whole value of the integral of primary current is exciting current, and will flow through the differential circuit. This integral is easily evaluated and can be shown to be (see appendix I):

$$\int_{t=(n+1)T_0}^{t=nT_0} i dt=IT_0\epsilon^{-nT_0/T} \qquad (7)$$

for any given cycle, n. Now, if the area under the exciting wave is $IT_0\epsilon^{-nT_0/T}$ according to (7), the magnitude of its peak value can easily be determined, if the assumption is maintained that the exciting current will appear as a half sine wave. The area under a half sine wave is (see appendix I):

$$A=\frac{PT_0}{\pi} \qquad (8)$$

where

P = peak value
T_0 = time of one cycle

If the area is given by (7), the peak value can be obtained from (8) and (7).

$$P=\frac{\pi A}{T_0}=\pi I\epsilon^{-nT_0/T} \qquad (9)$$

This expression for value of any exciting current peak at the nth cycle can be very quickly evaluated.

Determination of the time at which the saturation value of flux is reached can be made from equation 4. This equation cannot be solved for t as it stands, but if we make the pessimistic assumption that the sinusoidal component is always at its maximum value—

$$\frac{R_2\sin\omega t}{\omega}=\frac{R_2}{\omega}$$

then the equation can be solved for t, giving

$$t=-\frac{T}{0.434T_0}\log\left[1-\frac{\beta_s NA}{10^8R_2TI}+\frac{1}{\omega T}\right] \qquad (10)$$

If an impedance, Z_D, is connected into the differential circuit, it obviously will reduce the differential current. If the resistance were zero, the effect of inductance would be to reduce the variation in current, but to allow about the same magnitude of d-c component. If the inductance were zero, the resistance would continuously oppose the current, reducing it at every point on the wave.

If the differential current is calculated on the basis that the inductance in the differential circuit is negligible, the calculated value will certainly be somewhat too high, and the result will be in error on the conservative side. Referring to figure 9, we can rewrite (5)—

$$e_s=\frac{Nd\phi}{dt}10^8=R_2i_2-R_Di_1 \qquad (11)$$

Considering, as before, that ϕ will have to be the same, and equal to ϕ_s at the end of each cycle, it can be shown that (appendix II) the differential current will be a fraction of the value calculated from the assumption that the resistance in the differential circuit is zero, or

---

* $L_s\frac{di}{dt}$ may be included in this equation, but it can be shown that the resulting integral L_si will be negligible for any usual problem.

$$P = \pi I \epsilon^{-nT_0/T} \frac{R_2}{R_D+R_2} \text{ (peak amperes)} \qquad (12)$$

The methods used may seem to lack mathematical rigor. Indeed they do, but the assumptions are all uniformly pessimistic, and cannot well cause errors which destroy the practical value of the result. Comparison with tests show that the results are sufficiently accurate to be useful.

Relay Characteristics

The operating characteristics of relays are usually given in terms of symmetrical sine-wave quantities. Also, when current-time curves are taken, the current is usually left on until after the contacts have closed and the time determined. Consideration of the characteristics of the expected differential current reveals at once that it is not always sinusoidal nor symmetrical, and that it does not necessarily last for a length of time sufficient to cause the relay contacts to close, depending, of course, upon the time setting of the relay being used. For the differential problem, additional data are needed. These cover relay performance on altered wave forms involving various amounts of d-c and current-time curves wherein the current is applied only for a limited time. The latter curves will be termed "impulse curves" for convenience.

It is impossible to duplicate in the relay testing laboratory all of the possible currents which may occur in the differential circuit when all the variations between applications and between different possibilities for one application are considered. The best that can be done is to take data of a general nature which may be approximately interpreted for the particular application. Consideration of a large number of test oscillograms lead to the following conclusions:

1. The differential current for two or more cycles may be fairly represented in many cases by a fully and continuously offset sine wave. These few cycles, then, represent those test conditions wherein the harmonics present in the differential current are of minor consequence. The condition is easily set up by passing both steady-state direct current and sine-wave alternating current through the relay coil at the same time.

2. Subsequent cycles of the differential current may be fairly represented by half-wave rectified current. This approximation is sufficiently accurate until the differential current has subsided to a point where it is negligible in comparison with the original peak values.

A comparison of a standard current-time curve with impulse curves is given in figure 8 for a standard-type *COH* overcurrent relay. Each of the four curves was taken with the same tap and time-lever setting. The abscissas are plotted in terms of peak amperes rather than rms amperes in order that the approximate formula (9) or (12) for differential current may be most useful. Curve *a* is the usual current-time curve where the current is not interrupted until after the contacts close. For curve *b*, however, sine-wave 60-cycle current was applied only for the length of time shown by the time scale, and then interrupted. After the current was interrupted, the contacts closed due to kinetic energy stored in the disk. The total elapsed time from the application of current until the contacts closed is not shown by the curve at all. Thus, this curve is an "impulse curve", indicating a product of current and time which will store just sufficient kinetic energy in the relay disk to cause the contacts to close. Curve *c* is a similar impulse curve, except that half-wave rectified current was used. Curve *d* is a similar curve for a fully offset sine wave, where the direct current through the relay was made equal to 1.414 times the a-c sine-wave amperes. Curves *c* and *d* compared with curve *b* show the effect of a d-c component. Also, for the same peak-current values, curves *c* and *d* have less rms and 60-cycle component values. Curves *c* and *d* differ from each other because of the proportion of the direct current being different and because there are harmonics in the half-wave current.

Confirming Tests

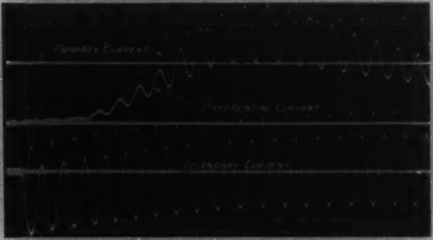
The approximate methods of calculating the current-transformer performance, as given, and the proper interpretation of the results in terms of impulse characteristics of the relays would have no value, of course, if it were not possible to verify the predictions made by means of suitable tests. Confirming tests have been made with results as given below.

Test Setup

Figure 9 shows the essential details of the test setup which was used. The circuit for demagnetizing the current transformers between tests is not shown. The nonsaturating current transformer shown was liberally designed so that it would not saturate under any of the test conditions. For this reason, the oscillographic record of *i* was taken as the true picture, in terms of the secondary, of the primary current. At the same time, the current, *i*, may be taken to represent the total output of any number of current transformers carrying current into a bus for an external fault, as in figure 1, on the basis that these current transformers do not saturate. This is a legitimate simplification of test setup, since nonsaturation of the input current transformers gives the maximum difference current, i_1, for a given saturation of the outgoing current transformer. Thus, the most pessimistic condition is arrived at at once with a decided simplification of test.

The resistor, R_2, was used to obtain various degrees of saturation of the test current transformer. The resistor, R_D, was

Figure 7. Test oscillogram showing error current with high percentage of direct current



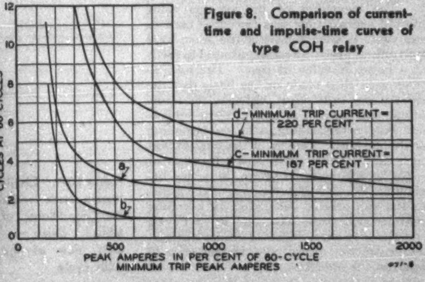


Figure 8. Comparison of current-time and impulse-time curves of type COH relay

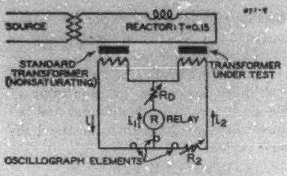

Figure 9. Diagram of test circuit

used to explore the possibility of preventing the false operation of a simple overcurrent differential relay by this means, and to check the accuracy of equation 12 showing the reduction in differential current expected.

As usual in tests of this kind, the current wave shape which can actually be obtained is not the perfect shape assumed in the theory, and the test results have to be properly interpreted to take the actual variation into account. The actual wave departs from the theoretical as follows:

1. It is never perfectly offset.

2. The output from a power transformer will contain not only a d-c component in proportion to the primary d-c component, but also a secondary d-c component determined by the constants of the secondary circuit. As a result, the secondary current, if initially offset on one side of zero, always becomes slightly offset on the opposite side before the transient finally disappears. The apparent decrement toward the end of the transient is higher than at the beginning, and higher than would be predicted from the true time constant L/R of the circuit.

3. There seems to be a higher decrement over the first cycle of current, probably due to the contact not being solidly closed initially.

The test results were, therefore, analyzed as follows:

1. The time constant was determined by plotting the logarithm of the average value of current. When the time constant departed to an appreciable extent from the true value (toward the end of the transient) the test and calculation do not agree, and this fact was simply accepted as unavoidable.

2. The logarithm of the average value plotted against time was projected back to the value it should have if the wave were fully offset, and it was always found to occur at a negative value of time. The calculations were then made on the basis that the current was fully offset, but that the transformer flux started at zero at some equivalent time corresponding to the real beginning of the current. That is, if the current was such that it would have been fully offset at -1.0 cycle (one cycle before the actual beginning) the time of saturation of the transformer can still be calculated by assuming that the flux starts from zero at $t=1$ cycle and the successive values of differential current calculated using $n+1$ instead of n in equations 9 and 12.

* n_{osc} denotes the number of the cycle on the oscillogram.

† n_{eff} denotes the number of the cycle on counting from time, $t=-1.0$ cycle where the current would have been fully offset.

** The reciprocals indicate a percentage of the energy required to operate the relay. Thus, if three cycles of a given peak current are required to close the contacts, then each peak delivers one-third of the total energy needed.

This sort of interpretation is awkward and not as straightforward and clear as might be desired, but is hardly to be avoided. If an a-c generator is used to supply the current, the difference between transient and subtransient reactance will reduce the initial a-c component, with the result that a wave which is initially fully offset may be more than fully offset during the second or third cycles, which will also require interpretation. It is obvious that the possible impulses of differential current can safely be calculated on the basis that the a-c component is maintained at the value corresponding to the subtransient reactance. Therefore, whether the current source is a generator or a transformer, the calculated differential current will always be somewhat higher than the actual value, providing that the current is based on the subtransient reactance of the generator.

The perfect current transformer used as a standard had about ten times the cross section of core and about one-fifth the resistance in its circuit of the transformer under test, and calculation showed that its flux density never exceeded the value corresponding to maximum permeability, so that it can safely be considered to be perfect. The other transformers in an actual differential protection circuit may not be perfect. If they are not, the actual differential current will be even less, and a perfect transformer balanced against a poor one represents a worst possible condition.

Taking all these considerations into account, a large number of tests were made and compared with calculations.

Test Results

The first set of tests was made with negligible resistance in the differential

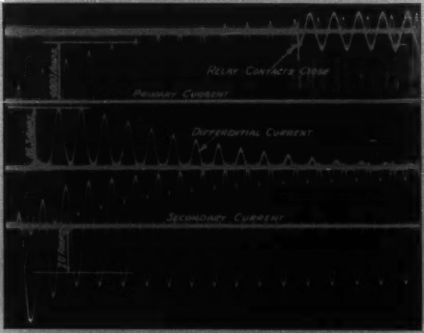

Figure 10A. Oscillogram made under the conditions of table I. Relay contacts close at the 12th cycle

circuit. The differential current was calculated according to equations 3 and 4, and a very good agreement obtained (figure 6). It was also calculated according to equation 12, and it can be seen that the equivalent half sine waves are much larger than test values to begin with, but are in fairly good agreement with test after the first few cycles.

The next step was to introduce resistance into the differential circuit. With a burden resistance of 0.82 ohm and a differential resistance of 0.38 ohm, the oscillogram of figure 10*A* was taken. The primary current lacked one cycle of being fully offset; that is, it would have been fully offset at −1.0 cycle. The time to saturation, calculated by equation 10, is 0.95 cycle. Taking this as 1.0, the equivalent time at which saturation would occur is actually about 2.0 cycles, and the successive calculated peaks (equation 12) of differential current are given in table I with the test values scaled from figure 10*A* for comparison.

The number of cycles which each peak would have taken to operate the relay (taken from figure 8) are given in columns 5 and 6 of table I, and the reciprocals of the numbers of cycles in columns 7 and 8. The sums of these columns are 1.74 and 1.17 respectively, and both indicate that the relay should operate. The relay actually operated about once in six times of application of current, and always operated when the current was offset as in figure 10*A*.

When the differential resistance is increased to 0.75 ohm, the oscillogram, figure 10*B* results and the corresponding peaks are given in table II. The sum of the reciprocal column based on calculated current indicates that the relay should operate. Actually, the relay could not be made to operate.

These tests indicate a considerable factor of safety. A large number of tests and calculations have been made, some of which show no factor of safety at all, and one test showed an actual operation when the calculated sum was only 0.8. This test indicates that if nonoperation is to be guaranteed, the sum of the reciprocal column should be held to something less than 0.8. A sum of 0.5 has been taken as a very safe value. If saturation occurs during the first two or three cycles, consideration of the possible differential current shows that each peak will have to last longer than one-half cycle and will, therefore, have a smaller peak value. Therefore, a larger factor of safety can be counted on if saturation occurs very soon than if it occurs later.

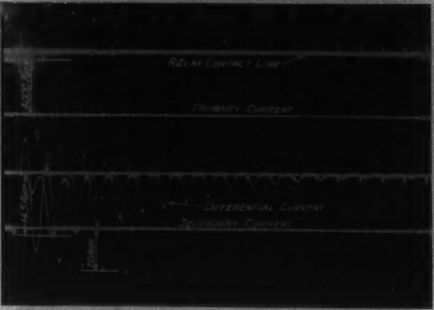

Figure 10B. Oscillogram made under the conditions of table II. Similar to table I, except that $R_D=0.75$ ohm. The relay does not operate

The test results which can be presented here are necessarily limited, so that they cannot adequately cover the entire range of possibilities. A large number of tests have been made, however, with sufficient results to justify the methods covered in this paper and are sufficiently general to warrant the following discussion.

In figure 10, for example, it is noted that the first few cycles of differential current are composed almost entirely of a d-c component and a sine-wave component. Obviously, its form is different from half wave, but the half-wave impulse curve of the relay was used in predicting relay operation. A better prediction could have been made by using impulse curve 8*d* for the first few cycles. However, curve 8*d* shows that the combined direct current and sine wave is less effective in operating the relay, and it is thus concluded that the use of curve 8*c* errs on the conservative side. From the point of view of simplification, as well as insuring that errors will always be on the conservative side, it is better to use curve 8*c* only, neglecting curve 8*d*.

Other Relays

The tests described were made with a simple overcurrent relay. In many cases, such a relay is not adequate for bus differential protection. The type *CA*-6 relay, which is a ratio-differential relay of the variable-ratio type, may be used where the requirements are more severe. With this relay, the same method of calculation of the peak values of the differential current may be used, of course. In considering the impulse characteristics, however, the effect of through fault current restraint is very important and helpful in allowing a much greater degree of current transformer saturation without causing a false tripping operation for a through fault. The impulse curves for the type *CA*-6 relay are quite similar to curve *c* of figure 8, except that they are moved considerably to the right, even with moderate restraint values.

Conclusions

1. The methods of approximate calculations outlined provide a tool for the analysis of current-transformer performance which has not been available previously.

2. The resulting predicted current in differential relay circuits is sufficiently accurate

for determining relay schemes and settings because the approximations which it has been necessary to make have been uniformly made on the pessimistic side.

3. The use of impulse curves of relays is of material value in reducing the amount of safety factor to allow because of unknown factors.

4. It is felt that the agreement between calculated results and test results, while not perfect, is sufficiently close to warrant the use of the method by protection engineers. Because of the variations noted, however, it is recommended that a safety factor of about 2 should be applied in relay work.

Appendix I

Evaluation of

$$\int_{t=(n+1)T_0}^{t=nT_0} i\,dt$$

$$i=I(\cos\omega t-\epsilon^{-t/T})$$

$$\int_{t=(n+1)T_0}^{t=nT_0} i\,dt=$$

$$I\left[\frac{\sin\omega t}{\omega}+T\epsilon^{-t/T}\right]_{t=(n+1)T_0}^{t=nT_0}=$$

$$IT\left[\epsilon^{\frac{-nT_0}{T}}-\epsilon^{\frac{-(n+1)T_0}{T}}\right]=$$

$$IT\epsilon^{\frac{-nT_0}{T}}\left[1-\epsilon^{\frac{-T_0}{T}}\right]$$

T/T_0 must be at least 3 in any problem of importance, because if the transient has a time constant less than three cycles long, it may usually be neglected. Hence, T_0/T will be less than 0.33 and if we write the series for $\epsilon^{-T_0/T}$:

$$\epsilon^{-T_0/T}=1-\frac{T_0}{T}+\left(\frac{T_0}{T}\right)^2\cdot\frac{1}{\underline{|2}}\ldots\text{etc.}$$

and

$$\frac{1}{\underline{|2}}\cdot\left(\frac{T_0}{T}\right)^2$$

and higher terms can be neglected.

Hence:

$$\int_{t=(n+1)T_0}^{t=nT_0} i\,dt=IT_0\epsilon^{-nT_0/T}$$

Evaluation of area under a half sine wave of peak value P:

$$\text{Area}=P\int_{t=0}^{t=\pi/\omega}\sin\omega t\,dt$$

$$=P\left[-\frac{\cos\omega t}{\omega}\right]_0^{\pi/\omega}$$

$$=\frac{2P}{\omega}=\frac{2P}{2\pi f}=\frac{PT_0}{\pi}$$

If the area of the integral

$$\int_{t=(n+1)T_0}^{t=nT_0} i\,dt\doteq IT_0\epsilon^{-nT_0/T}$$

is to be set equal to the area under the equivalent half sine wave, PT_0/π:

$$\frac{PT_0}{\pi}=IT_0\epsilon^{-nT_0/T}$$

the equivalent peak value is $P=\pi I\epsilon^{-nT_0/T}$.

Appendix II

Derivation of equation 12, considering effect of resistance in differential circuit: Continuing from equation 11, and following the same reasoning as in going from equation 5 to equation 7:

$$e_s=N\frac{d\phi}{dt}10^{-8}=R_2i_2-R_Di_1$$

or

$$N\frac{d\phi}{dt}10^{-8}=R_2i_2-R_Di_1$$

$$N\phi=N\int d\phi=0=R_2\int i_2dt-R_D\int i_1dt$$

$$\int i_2dt=\frac{R_D}{R_2}\int i_1dt$$

but

$$i_1=i-i_2$$

and

$$\int i_1dt=\int i\,dt-\int i_2dt=\int i\,dt-\frac{R_D}{R_2}\int i_1dt$$

Then

$$\int i_1dt=\frac{R_2}{R_2+R_D}\int i\,dt$$

As in appendix I, if we express the area,

$$\int_{t=(n+1)T_0}^{t=nT_0} i_1dt=\frac{PT_0}{\pi}$$

the equivalent half sine wave and

$$\int_{t=(n+1)T_0}^{t=nT_0} i\,dt=IT_0\epsilon^{\frac{-nT_0}{T}}$$

we have

$$\frac{PT_0}{\pi}=\frac{R_2}{R_2+R_D}IT_0\epsilon^{\frac{-nT_0}{T}}$$

and

$$P=\frac{R_2}{R_2+R_D}\pi I\epsilon^{\frac{-nT_0}{T}}\qquad(12)$$

Electric Braking for Railroad and Urban Transit Equipment

F. H. CRATON
MEMBER AIEE

F. M. TURNER
NONMEMBER AIEE

THE PURPOSE of this paper is to outline the present status of electric braking in the railroad and urban transit fields and to point out possible solutions of future braking problems particularly those arising from increasing speeds.

General

The science of train braking has progressed steadily with the development of railroad transportation. Improvements in air brakes along with improvements in motive power and rolling stock have made possible the steadily increasing speed and length of trains; in fact, the railroad industry as we know it today. With the exception of a few railway electrifications where regenerative electric braking has been applied, this entire development of braking on the railroads of this country has been, until very recently, that of the compressed-air system.

As the speed and length of trains have increased, the braking problem has become more and more difficult of successful solution. In freight-train operation, the problem is accentuated more by the length than the increased speed and has been one more of control than of dissipation of energy. This is because maximum speeds have been restricted both by tonnage handled per locomotive unit and by the design of rolling stock used. On the other hand, length of trains has increased to such an extent, it has been difficult to transmit the braking impulse from the locomotive to 100–150 cars in such a way as to avoid undesirably variable response, rough slack action, and damage to equipment and lading. A program is now under way involving application of improved brake equipment to approximately 2,000,000 freight cars to eliminate these conditions.

In passenger equipment, the problem of braking is more affected by increased speed than increased train length. A 20-car train is about the maximum handled and most trains are further restricted by traffic requirements and station-platform limitations. The use of spring buffers and other means of either controlling or eliminating slack, simplify the problem. The use of electropneumatic brakes on unit trains effects instantaneous transmission of the braking impulse to every car. The difficulty arises from the peak speeds now encountered—100 miles per hour or more—where desired retardation rates, braking ratios, shoe pressures, and rate of energy dissipation greatly exceed past requirements for safe and economical operation.

Associated with the high-speed deceleration problem is the requirement of higher-speed operation on down grades where, in mountain territory, railroad profiles require miles of continuous operation descending two per cent grades, imposing a heavy load on the brake equipment from the standpoint of continuous energy dissipation that is almost directly proportional to the higher speed.

These problems are serious and much research and development work is being done by the air-brake manufacturers to cope with them. Tied in with these problems is the question of the deleterious effect many claim high-speed braking has on wheel life and performance. This has led to experiments with various types of nontread friction brakes.

In the urban transit field schedule speeds have also been increased with a corresponding increase in braking rates as well as acceleration. While speeds are much lower than for heavy railroad operation, the requirement for more rapid acceleration is, nevertheless, an important factor. At the same time relief from excessive heating of the wheel treads by mechanical braking is essential to economical maintenance and safe operation.

Unlike heavy railroad operations, urban vehicles rarely require braking on long grades but are concerned principally with frequent and rapid decelerations for stops. Dynamic or rheostatic braking systems and electromagnetic track brakes are now being extensively applied to urban transit vehicles.

The successful dissipation of large amounts of energy is not the only problem in high-speed braking. Due to the high retardation rates required to hold stopping distances within prescribed limits, it is desirable to take advantage without wheel sliding of all of the wheel-rail adhesion possible throughout the complete deceleration. Opposed to this, is the fact that the braking force is directly affected by many transient phenomena, which cause it to change many times during a deceleration. Not only does this make necessary the use of devices to alter the braking ratio during a maximum deceleration, but also, because these phenomena are likely to differ in magnitude on different axles in the train due to condition of wheels, shoes, brake rigging, etc., the brake application should be such as to prevent wheel sliding on the axle most susceptible to it. Devices are now being tried which anticipate wheel sliding on each axle and automatically ease the brake shoe pressure when wheel sliding is imminent.

A precept which has governed the design of new braking equipment is that improvements must be of such a nature that they will function in complete harmony with existing apparatus and thus preserve the enormous investment in equipment already in service.

The foregoing remarks give a rough idea of the magnitude and complexity of the braking problem, particularly with respect to high-speed passenger operation. The following discussion will attempt to show the part which various forms of electric braking are playing in the railroad picture and what effect they may have on the further development of means to cope successfully and economically with this increasingly difficult problem of high-speed braking.

Paper 40-28, recommended by the AIEE committee on transportation, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 16, 1939; made available for preprinting December 28, 1939; released for final publication March 21, 1940.

F. H. Craton and F. M. Turner are in the transportation department of the General Electric Company, Erie, Pa.

Braking a train from high speed to standstill usually takes the form of unproductive liberation of heat by the dissipation of kinetic energy created during acceleration. Braking on a heavy downgrade at constant speed produces the same result by dissipating potential energy created by hauling the train uphill previously. The natural function of a wheel appears to be to roll under load and not act as a medium for the dissipation of excessive amounts of energy at excessively high rates such as encountered frequently in the retardation of modern trains. Even though wheels have been employed at this task with considerable success, the demands have reached a point where other means are being considered for the dissipation of this energy.

Regenerative Electric Braking

The ideal braking system would be one which would transform into useful work all available kinetic and potential energy in the train not absorbed by normal train friction. As this would require a system of 100 per cent efficiency, it is obviously impossible but from a practical standpoint, such a system for constant-speed retardations is approached by regenerative electric braking which is available for most forms of straight electric locomotives, and is one of the several advantages which railroad electrification in general makes available.

This type of braking has been used on mountain electrifications exclusively since the benefits have been greatest in retarding heavy trains while negotiating long steep grades. Wherever used, this system has been very successful and has resulted in the following advantages:

Saving of approximately 15 per cent of total power required without regeneration, and 60 per cent on two per cent grade sections.

Elimination of brake shoe, wheel, and brake rigging trouble with attendant reduction in maintenance costs.

Smooth, continuous braking effort over long periods eliminating surges in speed with resultant wear and abuse of equipment.

Increased safety because the air brake is held in reserve so that in case of emergency stops, the air-brake system is charged and wheels and brake shoes are cool.

Increased comfort to passengers due to constant speed on grades and absence of noise due to grinding of shoes on wheels.

With this system, the braking power is limited by the driver weight of the locomotive and the capacity of the traction motors. In operation involving retardation of the train downgrade at constant speed, due to the fact the braking effort necessary is equal to the required tractive effort to haul the train up the grade minus twice the train friction, modern regenerative locomotives are capable of handling with leeway, any train downgrade which they can handle up the same grade. Grade sections also frequently include heavy curves which are fully compensated and this factor further reduces the braking necessary to hold a descending train.

Take for example a passenger train of 1,000 tons gross weight hauled by a 3,000-volt d-c locomotive recently put into service. The locomotive weighs 185 tons with 135 tons on drivers. The motoring and braking characteristics are shown in figures 1 and 2 respectively. The tractive effort required to handle this train up a two per cent grade is 47,000 pounds or 17.4 per cent adhesion, which gives a balancing speed of 50.3 miles per hour in the highest-speed motor combination. Retarding this same train down a two per cent grade requires 31,000 pounds braking effort or 11.5 per cent adhesion, which is attainable up to 67.5 miles per hour.

Track conditions, particularly curvature, will, of course, govern speeds in this type of operation, but the foregoing example shows the possibility of regenerative electric braking with a modern high-powered locomotive with respect to high-speed operation in heavy-grade territory. In this example, additional electric braking power is available if required, and with the air-brake system backing up the regenerative brake, safety is assured.

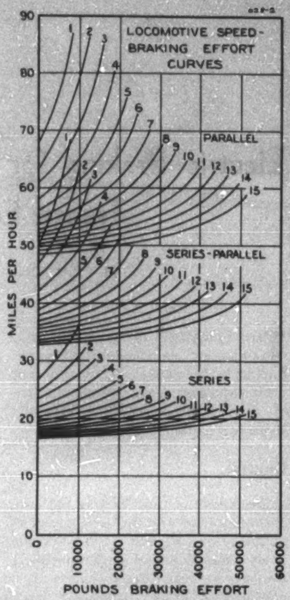

Figure 2. Speed-braking effort curves for a 185-ton six-motor electric passenger locomotive with regenerative braking

The regenerative electric brake can be used to advantage sometimes for light decelerations, the extent depending upon the grade, weight of train, and required decelerating rate. The bunching of slack and the smooth, quiet application of retarding effort is both beneficial to equipment and, in passenger service, a distinct advantage particularly to patrons in sleeping cars.

For retardation cycles approaching a full service or emergency application with air equipment, the regenerative brake, which is available on the locomotive alone, is entirely inadequate because of limitations in both driver weight and electrical capacity. For such decelerations, it is necessary to take advantage

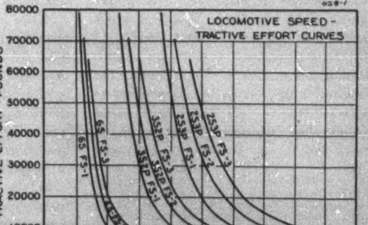

Figure 1. Speed-tractive effort curves for a 185-ton six-motor electric passenger locomotive

of the entire adhesive weight of the train. To appreciate this fully, consider the conditions involved in decelerating a 1,000-ton train from 80 miles per hour to standstill on level track.

At 80 miles per hour this train possesses a kinetic energy of approximately 428,000,000 foot-pounds, ignoring the rotational energy of wheels and axles. With a full service application of the air brakes, the deceleration will be at approximately two miles per hour per second average to standstill. On the basis of the train resistance cancelling the rotational energy during deceleration, which is essentially true, the average braking effort during the retardation cycle would be 182,000 pounds and the *average* dissipated horsepower 19,400. Taking the powerful locomotive represented by figures 1 and 2, this corresponds to a wheel-rail adhesion of 67 per cent and a braking horsepower 277 per cent of the maximum available.

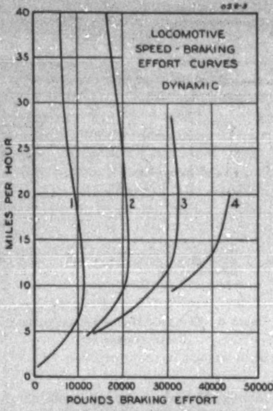

Figure 3. Speed-braking effort curves for a self-propelled locomotive with dynamic braking

In an emergency application at three miles per hour per second average deceleration, the average braking effort becomes 273,000 pounds, and the average dissipated horsepower, 29,100, corresponding to 101 per cent adhesion and 415 per cent of the maximum available braking horsepower of the locomotive.

These decelerations, which are not based on unusually severe conditions of either maximum speed or weight, give another insight into the magnitude of the energy to be dissipated and the resulting forces involved in the braking of high-speed modern trains.

Dynamic Electric Braking

Self-propelled locomotives using electric drive such as the Diesel-electric and steam-electric types can be equipped with dynamic braking which does not differ essentially from regenerative electric braking except that the energy must be dissipated in some manner on the locomotive rather than returned to the distribution system.

In some respects the dynamic electric brake has advantages the d-c regenerative brake does not have, in that the dynamic brake is flexible as to its characteristics. There are two types of braking characteristics, the holding brake and the stopping brake. The former has variable braking effort at constant speed and the latter, constant braking effort at variable speed. The regenerative electric brake on d-c equipment is of the holding-brake type inherently because it is tied down to constant voltage operation. The dynamic electric brake, however, can be designed to produce any desired characteristic by suitable arrangement of circuits, excitation, and external resistor values.

Figure 2 shows the characteristic curves of the regenerative electric brake on a d-c locomotive. The relatively flat shape means the locomotive can descend a variable profile at practically constant speed, automatically adapting itself to the changes in braking effort required.

Figure 3 shows a dynamic braking characteristic that is vertical and ideal for applying constant braking effort automatically throughout a deceleration. This can be approached with the regenerative brake in figure 2, but only by a skilled operator through constant manipulation of the braking controller, including shifting the motor combinations when required.

The 5,000-horsepower steam-electric locomotive built for the Union Pacific system, has a unique application of dynamic electric braking (figure 4). The unusual feature is the method of dissipation of electric energy generated during braking. The energy is delivered to a resistor consisting of sections of seamless stainless-steel tubing, through which water is circulated from the main power plant, the water being heated and in heavy braking duty partially converted into steam. The outlet of the resistor is connected to a separator from which hot water is returned to the hot well and steam to the main condenser.

The electric brake may be used alone or in conjunction with the air brakes. When used alone or with the air brake up to 48 pounds brake-cylinder pressure, the output is limited automatically to 4,800 kw to protect the motors from continuous overload down long mountain grades. From 48 to 100 pounds brake-cylinder pressure, indicating a stop is imminent and the demand for power limited in time, the output of the electric brake is graduated automatically up to 7,200 kw at the 100-pound cylinder pressure which corresponds to an emergency application on a modern electropneumatic straight air equipment as used on streamlined trains.

To date there have been no applications of dynamic braking to Diesel-electric locomotives in main-line service, although there is no reason why such braking cannot be applied. Experience with this type of braking on the Union Pacific steam-electric locomotive has emphasized the advantages of the system in retardations at constant speed or moderate decelerations, as well as safety at higher speeds in downgrade operation.

On a Diesel-electric the energy can be absorbed in resistors and the heat ultimately released to atmosphere through a system utilizing the engine cooling water and radiators. As alternatives, air-blast resistors might be used or resistors cooled by a separate fluid system employing a synthetic liquid of desirable characteristics with respect to specific

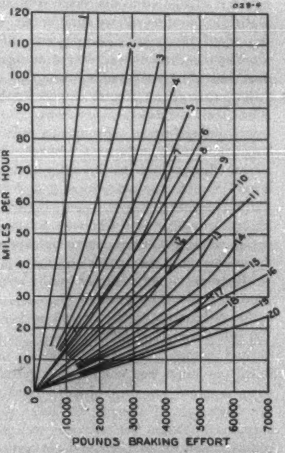

Figure 4. Speed-braking effort curves for 5,000-horsepower steam-electric locomotive (dynamic braking)

heat, boiling and freezing points, dielectric strength, inflammability, etc.

A miniature edition of such a dynamic brake was put in service recently on a 400-horsepower 20-ton Diesel-electric rack-rail locomotive for pushing a 12-ton observation car up and retarding it down the Manitou & Pikes Peak Railway which negotiates Pikes Peak in Colorado. The braking problem on this nine-mile road is severe because the average grade is 16 per cent and the maximum 25 per cent and absolute reliability is essential. The use of dynamic braking, in which power is dissipated in air-cooled resistors in the locomotive allows full control of the speed throughout the descent with the dynamic brake alone except at stopping when this brake fades out.

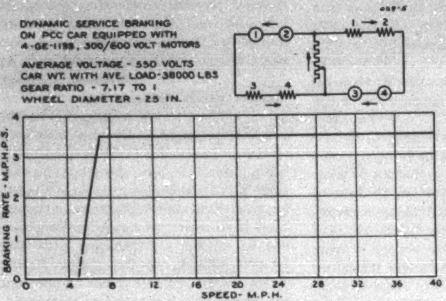

Figure 5. Dynamic service braking curve for PCC car

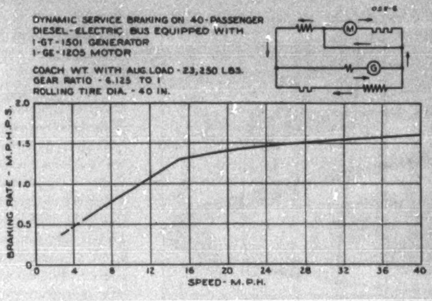

Figure 6. Dynamic service braking curve for Diesel-electric bus

The use of an electric brake would eliminate immediately all problems arising from sliding-friction phenomena, wheel slipping, and temperature changes in shoes. Because of its prompter action, fewer variable characteristics, and flexibility, it is effective more quickly than the air brake and can be used as well to assist the conventional brakes where high-speed demands exceed their capacity.

Electric braking so far has hardly been tried in the streamliner field where speed is the outstanding factor. Today we hear 100 miles per hour talked of freely as a normal nominal top speed just as 60 miles per hour was commonly referred to as a measuring stick of high speed a few years ago. Tomorrow 100 miles per hour maximum on the rails may well be common, and we shall be looking at higher speed levels again as indicative of the trend of ultramodern railroad equipment. Even today, the modern self-propelled locomotive with electric drive is geared for a peak speed of 120 miles per hour. As these top speeds increase, the braking problem becomes more and more acute. The kinetic energy in a train at 140 miles per hour is about double that in the same train at 100 miles per hour. As this trend to higher speeds develops, the necessity for new braking methods will become increasingly pronounced. The electric brake is a potential candidate to meet this necessity; in fact, it may open the door to ultrahigh-speed operation, for without suitable braking equipment, such operation is impractical.

Electric Braking in Urban Transit Service

In recent years, electric braking also has been used in urban transit service, which is quite different from heavy main-line railroad operation. Urban service involves relatively light vehicles, such as the Electric Railway Presidents' Conference Committee or "PCC" car, the single-motor trolley coach, and the gas-electric or Diesel-electric bus.

The PCC car utilizes entirely new propulsion equipment to obtain high rates of acceleration and braking, and resilient wheels which have rubber inserts between the wheel tire and hub to reduce wheel and rail noise. This design was a factor in the adoption of a braking system comprised of dynamic braking, magnetic track brakes, and conventional air-operated wheel brakes properly blended by a single brake pedal.

During a typical service stop of a PCC car weighing approximately 38,000 pounds with seated load and decelerating at $4^3/_4$ miles per hour per second, the traction motors contribute $3^1/_2$ miles per hour per second of dynamic braking and the magnetic track brakes $1^1/_4$ miles per hour per second deceleration from 40 miles per hour down to approximately 7 miles per hour. At this speed the dynamic braking fades out rapidly and the air brakes are automatically engaged to assist the magnetic track brakes in maintaining the braking rate to standstill. A feature of this braking sequence is the fact that the air brakes are called for at the same pedal by which dynamic braking is established, but the air brakes are held off automatically so long as the dynamic braking builds up to the desired rate. Thus, if the dynamic brakes should fail to build up for any reason, the air brakes would be available immediately to assist the magnetic track brakes in braking the car. Emergency stops at a rate of 7 to 8 miles per hour per second are obtained by increasing the dynamic braking to 4 miles per hour per second and the magnetic track brakes to 3 or 4 miles per hour per second deceleration, by depressing the brake pedal to its lowest position. An infinite number of intermediate braking rates between one mile per hour per second and emergency rate are available by depressing the brake pedal a corresponding amount.

Dynamic braking was selected as the primary brake on PCC cars because it is entirely independent of the trolley power in case of dewirement and because it requires relatively little control equipment in addition to the accelerating control, much of which is also used during the braking cycle. In addition, an emergency dynamic braking position is provided on the manually operated motor reverser. When the reverser is placed in this position, the traction motors are short-circuited to provide a very effective dynamic emergency brake if all other brakes should fail.

Each magnetic track brake consists of a large electromagnet mounted on a long, narrow shoe that is suspended parallel to and directly over the rail between the two wheels on each side of each truck. Four such magnet shoes are mounted on a car. When the electromagnet coil is energized, the shoe is pulled against the rail by its own magnetic action and the resultant friction of the brake shoe on the rail exerts a braking effort on the car. The relative effect of this retarding force is dependent upon the magnetic strength of the electromagnet coil, which is controlled by depressing the brake pedal. The track-brake coils are energized from a storage battery in order to make this brake also independent of the trolley power in case of dewirement. This brake is not usually cut off before standstill is reached, nor does it fade out at low speeds. However, provision is made to release it when the brake pedal is latched down to continuously engage the air brakes for prolonged parking, in order to eliminate needless drain of energy from the battery.

The use of electric braking as the primary brake on PCC cars eliminated the problem of using air-operated wheel brakes for service stops at high rates of deceleration with the attendant dissipation of large amounts of heat in the car wheels. In fact, some of the newest cars use a spring-applied clasp brake to supplement the electric brakes at low speeds and for parking, and thus eliminate entirely the use of air-operated wheel brakes. The same principles of electric braking utilized so successfully on PCC cars have recently been applied and have materially simplified the problems of equalization and prompt response of braking effort on all axles of a multisection subway-elevated train (figures 5 and 6).

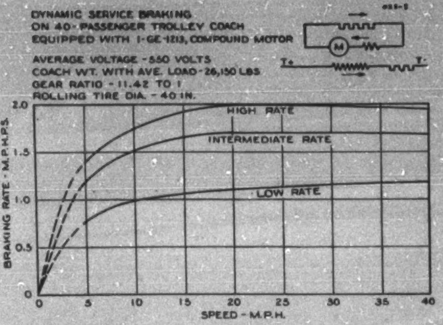

Figure 8. Dynamic service braking curve for single-compound-motor trolley coach

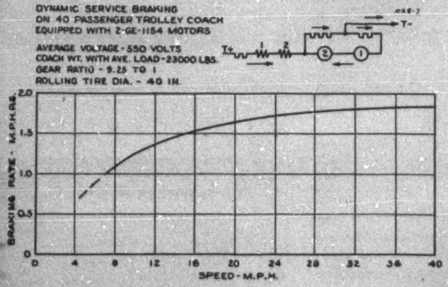

Figure 7. Dynamic service braking curve for two-motor trolley coach

Electrically propelled automotive-type urban transit vehicles, particularly the trolley coach, have presented a more serious braking problem than mechanically driven busses, due to the higher rates of acceleration and deceleration demanded from electric drive and due to the free-wheeling characteristic of electric drive in which there is no engine compression to assist the wheel brakes. The use of higher ratios (power-to-weight) with electric drive in the last few years, coupled with the fact that the physical size of wheel brakes has reached practical limits, led to the introduction of the compound-wound trolley-coach motor and automatic control equipment designed especially for regenerative and dynamic braking and speed control, and to the development of new series-wound motors and control equipments designed especially for dynamic braking.

It is characteristic of the compound-wound motor that, if the shunt-field strength is increased while motoring at a given speed, the motor, driven by the inertia of the load, begins to regenerate and exert a braking effort on the load until a lower balancing speed corresponding to the stronger shunt-field strength is attained, at the same time returning power to the line.

This principle of shunt-field control is utilized with the modern compound-wound trolley-coach motor to provide a number of balancing speeds over the upper half of the vehicle's speed range, with regenerative braking automatically obtained during deceleration from one balancing speed to another or while holding the coach at any one of these balancing speeds during descent of a grade.

The compound-wound motor with the shunt-field winding separately excited from the trolley has ideal characteristics for dynamic braking (figure 8). By opposing the series and shunt fields, a differential action is obtained which prevents the imposition of excessive strains on the rear axle or gearing. Dynamic braking and air braking are applied by a single pedal. Maximum dynamic braking is obtained at approximately one-half pedal travel; and at the same time a small amount of air is admitted to the brake cylinders. Further movement of the pedal maintains maximum dynamic braking until approximately 85 per cent of the air braking is being applied. Dynamic braking is then reduced to the minimum and 100 per cent air braking applied. This operating sequence permits maximum utilization of dynamic braking without applying excessive braking to the rear wheels during an emergency stop.

Paralleling the development of the compound-wound motor is a new series-wound motor for trolley coaches which has been designed especially for dynamic braking. This development was made possible largely by the introduction of a practical, automatic acceleration control which has been adapted for use during dynamic braking automatically to commutate the braking resistance in series with the motor to hold the desired acceleration rate. An infinite number of intermediate braking rates between the minimum and the maximum are available merely by depressing the brake pedal a corresponding amount. The same brake pedal also controls the air brakes, which may be applied simultaneously with the dynamic braking to provide higher braking rates than are possible with dynamic braking alone, or to assume the braking duty at low speeds below which the dynamic braking automatically fades out.

The past year or two has also advanced the application of electric service braking to existing cars and trolley coaches of older design. The scheme most universally employed for this purpose consists essentially of connecting load resistors across the motor armatures and connecting the armatures in series with the motor fields in such a manner that, when the fields are excited from the trolley, the generated voltage of the motor armatures opposes the applied trolley voltage. This connection results in a differential action which automatically increases the field strength as the armature voltage decreases with vehicle speed in order to maintain a substantially constant rate of deceleration over a wide vehicle speed range. This form of dynamic braking is advantageously applied to older-type cars and trolley coaches having nonautomatic control and excess motor capacity.

Dynamic electric holding brakes were practically standard equipment on the earliest gas-electric busses with dual-motor drive, as these busses had only two-wheel mechanical brakes. However, the holding brake as applied to these vehicles was not designed to assist the wheel brakes during a service stop, but was intended merely for holding the bus at a predetermined speed on some specific grade. Since the introduction of the modern single-motor equipment for gas-electric or Diesel-electric busses was subsequent to the universal adoption of four-wheel air brakes for railless urban vehicles, the dynamic holding brake has been retained only where unusually long or severe grades are encountered, complete reliance being placed on the air brakes in most cases.

However, increased size of busses and installation of larger engines, as well as a demand for higher schedule speeds, have recently promoted the development of a fully automatic electric service brake to supplement the air brakes on modern gas-electric and Diesel-electric busses. This form of dynamic braking utilizes power obtained from the main generator to excite the fields of the traction motor, the armature of which has a braking resistor connected across it. The amount of motor field excitation taken from the generator is automatically regulated to maintain an approximately constant braking rate over the entire speed range of the bus. The electric braking may be applied whenever the engine throttle is returned to its idling position, in order to simulate the retardation effect of engine compression, or it may be applied by initial movement of the brake pedal. It is automatically cut off at low bus speeds. Test installations indicate a material improvement in the life and maintenance of the wheel brakes on Diesel-electric busses equipped with this type of dynamic service brake.

In all cases where modern electric service braking has been applied to supplement wheel brakes, the life and maintenance of the wheel brakes on electrically propelled vehicles has been equal to or better than the life and maintenance of wheel brakes on similar mechanically-driven equipment, in spite of the higher schedule speeds and higher deceleration rates normally used on electrically-propelled vehicles. The use of higher rates of electric braking on trolley coaches and on electrically-driven busses is not recommended, however, because the braking must all be done on the rear axle and would thus cause the rear wheels to assume a very major portion of the total braking duty. This would cause the vehicle braking characteristics to approach the obsolete performance standards of two-wheel brakes which, for obvious reasons, the industry saw fit to discard years ago.

Conclusions

Operating experience in recent years clearly establishes the importance of electric braking as a supplementary system both in heavy railroad operation and for urban transit. A continued demand for higher speeds is to be expected and the limitations of mechanical brakes without excessive weights and costs have already been indicated. Thus, electric braking may easily augment the increasingly drastic requirements of electric modern motive power.

Of the several types of electric brakes discussed, regenerative braking is available for electrified railroads or trolley-coach lines while dynamic or rheostatic brakes, eddy-current brakes, and magnetic track brakes can be applied as well to self-propelled vehicles. Under heavy braking conditions, regeneration returns appreciable amounts of power to the line. Exceptionally favorable conditions such as a three per cent continuous grade may return regenerated power amounting to as much as 70 per cent of that used for motoring.

Dynamic braking delivers electrical energy to resistors where it is dissipated in the form of heat. Eddy-current brakes accomplish the same result by use of a self-contained independent device attached to the motor frame and coupled to the armature shaft. Eddy-current brakes are operating successfully on rapid transit equipment but in general the extra cost discourages their general use. Dynamic brakes on the other hand make use of the existing motor as a generator and usually the resistor equipment normally used for acceleration.

Magnetic track brakes while simple and comparatively inexpensive are only justified where rapid and frequent decelerations are absolutely essential to the performance of a given schedule. Present applications are limited to PCC cars and rapid transit trains.

Network Coupling by Means of Static Electronic Frequency Changers

OTHMAR K. MARTI
FELLOW AIEE

DURING the last few years several attempts have been made, especially by some foreign railways, to find ways and means to feed their 11,000-volt $16^{2}/_{3}$-cycle railway trolley system directly from a commercial 50-cycle power source by means of a simple device, or then to have the locomotives equipped with such apparatus which would permit using power at the latter frequency fed directly to the trolley line. In other words, it was felt that many advantages could be gained if the trolley line could be fed, directly, or over a simple converter, from any commercial power network which would be adjacent to the railroad's right of way. This desire led to the development of the 50-cycle series commutator motor by the Siemens Schuckert Company, a 50-cycle converter cascade motor by the Krupp Company, and to the converter locomotive by Von Kando. It also led to the design by several companies in Europe of a locomotive with a built-in mercury-arc rectifier for converting the 50-cycle power fed directly to the trolley line into direct current suitable for standard railway motors.

Furthermore, studies were made using a commutatorless motor with a mercury-arc rectifier. The development of this motor, having no commutator but using a rectifier for commutation and able to operate on commercial frequency, was, however, abandoned in its early stages, as far as its use on a locomotive went. However, it may be said that since single-anode tank rectifiers of large capacity are now available, a more economical connection for the commutatorless motor could be employed than was considered when the first investigations were made.

The operation of these various systems proved successful from a technical point of view, but they were found less advantageous from an economical and maintenance standpoint.

At this time, as briefly referred to above, still another system permitting the use of power of conventional frequency was under careful consideration, namely, using a rectifier on the locomotive converting 50-cycle power fed directly to the trolley system into direct current and supplying it to standard railway motors. Finally four locomotives of this design were built. Three of them are operating on the Hoellental railroad system. This system was originally projected for a trolley voltage of 15 kv but had to be raised to 20 kv in order to compensate for the high inductive drop at 50 cycles. The locomotives were equipped with standard series motors, a rectifier and transformer, and devices for voltage control, etc. The 50-cycle power supplied to the trolley system from a conveniently available power line is stepped down and converted into direct current by the transformer and rectifier on the locomotive.

However, before the studies undertaken by four companies in connection with these locomotives were very far advanced, it was found that the grid control, which at first thought appeared extremely simple, became quite involved. One company even abandoned the idea of controlling the voltage by means of grids and introduced tap changing under load equipment for regulating the anode voltage of the rectifier, and thus in turn the direct voltage supplied to the motor.

Simultaneously with this development, attempts were made to develop a static frequency changer using grid-controlled mercury-arc rectifier-inverters (electronic rectifier-inverters). This method would also make it possible to take power from any commercial network, convert it and feed the trolley system with a frequency suitable for a-c railway motors.[1–6] Such devices would be static and some of them would permit flexible coupling between a three-phase 60-cycle, and, for instance, single-phase 25-cycle trolley systems. Tests[6] with such frequency changers were started over six years ago, and after extensive experiments with sets of a capacity of 500 to 1,000 kw, a commercial installation was finally erected near Basel, Switzerland, feeding power into the $16^{2}/_{3}$-cycle trolley system of the Wiesenthal Railroad, Germany, from a 50-cycle network.[8,17,18]

The object of this paper is to discuss such methods of frequency changing using electronic rectifier-inverters which would make it possible to transform three-phase power of 60 or 50 cycles into 25 cycles, the frequency commonly used by the railroads in the United States. The other systems as used today in Europe are briefly referred to and discussed only where they have a bearing on the systems suitable for obtaining 25-cycle power.

Rotating Versus Static Frequency Changers

The phenomena taking place during conversion of electric energy from one frequency to another will be discussed briefly in order that the arguments in favor of methods using electronic converters can be easily followed, and so that some of the theoretical considerations put forward in several articles referred to below can be fully appreciated.

We may recall the fact that the energy furnished by a three-phase network, with a symmetrical three-phase voltage system, normally supplies a constant power flow in spite of the fact that in each individual phase the voltage and current change according to a sine wave. Power from a single-phase network, however, pulsates with twice the frequency of the induced voltage and current, which, as is well known, is an inherent characteristic of such systems. The instantaneous power demands of the two systems are not equal. Therefore, the supply of power from a network of commercial frequency to a single-phase railway system, necessitating conversion of energy from 60 to 25 cycles, means the electrical coupling of two power systems, each of which has quite a different characteristic of its natural flow of energy.[9]

Let us first analyze the power relation in case a three-phase single-phase motor generator set is used for coupling such systems. The power absorbed by the motor from the three-phase 60-cycle system shall be assumed to be constant and is illustrated by T in figure 1*b*. T is the summation of the power furnished by each phase X, Y, W, of the three-phase system. The power demand of the single-phase network on the three-phase network is shown in figure 1 by curve S, which in case of a mechanical frequency changer will always be active. In other words, in such a frequency changer no reactive power can be transmitted from one to the other system, and the same condition holds true

for a circuit as shown in figure 2. From figure 1*a* it can be seen that the single-phase energy *S* pulsates about a mean value *T* with a frequency equal to twice that of the frequency of the current *i* and voltage *e* of this system. The mean power of the single-phase system must be equal to *T* as the loads of the two machines average the same over one cycle, but, as said above, are not the same at each instant of the cycle. It will therefore be seen that during certain intervals (*a*), for instance, single-phase energy equal to the horizontal hatched area will have to be supplied from a source other than the three-phase system, while during the intervals (*b*), the same amount of energy has to be absorbed and stored in some way or other in order that the three-phase energy supply may be constant (equal to *T*). In other words an energy reservoir will be necessary to balance the available and required power. Curve S_1 shows, for a few cycles, the magnitude of energy which has to be taken care of at each instant by certain means (accumulators) capable of absorbing and freeing energy.

In the case of a motor generator set the rotating masses will automatically take care of the excess energy during period (*b*) and release it during period (*a*). However, it must be realized that this will only take place if the speed varies or deviates from the mean value *N* as shown in curve *n* (figure 1*a*). In other words, during the interval (*a*), the speed of the rotating masses is being advanced, while during interval (*b*) the speed will decrease over the mean value *N*.

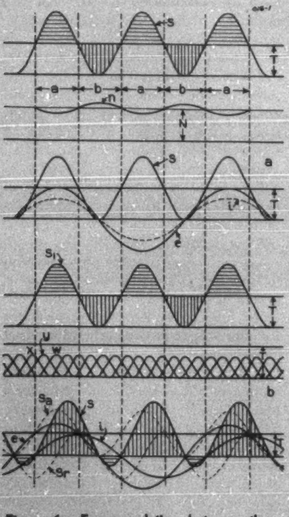

Figure 1. Energy relation between three-phase, single-phase systems of frequency converters

Therefore, a rotating frequency changer (motor generator set) is able, with its normally inherent rotating masses, to take care of the surplus, or lack, of energy as compared to the mean value *T*, since the rotating masses permit storing and supplying energy. The three-phase motor will, therefore, draw constant energy from the 60-cycle network in spite of the pulsating character of the single-phase load, but the speed will fluctuate slightly with the frequency of the pulsating single-phase load.

The power supply for conversion of three-phase to single-phase current by means of an electrically controlled rectifier-inverter is illustrated in figure 1*b*. The power demand *S* oscillates at twice the single-phase frequency as above, *T* being the mean value and S_a the active and S_r the reactive component of power demand from the single-phase supply. Both were taken to be equal, representing a power factor of approximately 0.7. In the case of a frequency changer using an electrically controlled rectifier-inverter, no inherent means are available to permit storing and releasing of power at the frequency impressed by the single-phase load characteristic. Therefore, with such equipment the power oscillations are transferred to the three-phase network, which will be loaded with currents departing from sine waves and of frequencies foreign to the network frequency. This will result in an increase in reactive power, harmonics, and a negative component in the three-phase current system which will in turn affect the efficiency factor.

The above condition can only be corrected if means are used to take care of the differences between the instantaneous power demands of the systems as is done inherently in the case of a mechanical frequency changer. Such energy-storing equipment can be built up using a battery of capacitors and reactors (a resonant circuit). However, due to the fact that the intermediate d-c circuit of such an electronic converter, see figures 3 and 4, has a superimposed alternating current of 360 cycles (if a 6-phase electronic converter is used) and 720 cycles (if 12 phases are used), the smoothing or storing equipment may have to be of fairly high capacity. The use of capacitors and reactors forming a resonant circuit, even if of large capacity, introduces very little additional losses, as the energy can be kept oscillating between capacitors and reactors, consuming very little power. In case it is found advisable that the single-phase power energy oscillations may partly be transmitted back to the three-phase system, in other words, if *T* may vary, then the capacity for the storing equipment (capacitors and reactors) becomes relatively small. However, due to the recent developments of static capacitors for power-factor-improving equipment, the cost of such storing equipment is no longer prohibitive, and enough capacity may be provided to obtain a constant energy flow from the three-phase network as shown by *T*.

Electronic Frequency Changer With Intermediate D-C Step

Flexible Indirect Coupling Between Systems

The simplest method for effecting a flexible coupling of a-c systems of different frequencies by means of electronic rectifiers and inverters is shown in figure 2. This system consists of a rectifier, a reactor, and an inverter. Three functions are necessary: First, the a-c power of 60 cycles is rectified into d-c power; second, the d-c power is inverted into 25-cycle single-phase power, and third, the difference between the instantaneous power demand of the single-phase system and the three-phase supply has to be balanced by an energy accumulator, which may consist of a reactor and a capacitor. The reactor

e_1, e_2, e_3, e_4, e_5, e_6, e_1, etc., represent phase voltages of the 60-cycle six-phase system. e_{1-1} and e_{2-1} represent voltage waves of the 25-cycle single-phase full-wave system. e_d represents the intermediate direct voltage of the rectifier inverter

is inserted between the rectifier and inverter, and takes care of the differences of the direct voltages e_{6-1} and e_{2-1}, figure 3. The voltages e_{6-1} and e_{2-1} refer to a six-phase rectifier system and a single-phase inverter system. For further data on rectifier and inverter operation, see bibliography.[13,14,26,28] The above arrangement does not allow reactive power to be fed back to the three-phase system, and only active energy can be transferred from the three-phase to the single-phase network. The reactive power would therefore have to be taken care of by a static or a synchronous condenser connected to the single-phase system.

The first two steps, namely, converting power from alternating current to direct current and from direct current to alternating current, have been done separately in many installations during the last few years and a great deal of experience was recently gained during extensive field as well as factory tests in connection with inversion of direct current to alternating current by means of grid-controlled rectifiers.[11,21,23] These tests have demonstrated that the flexibility between two a-c networks is fully maintained and no instability resulted no matter how large and sudden a change in frequency took place.

It may therefore be realized that at this time a frequency-changing set of great reliability can be built by utilizing the experience gained in some of the high-voltage rectifier and inverter installations briefly referred to later on.

Electronic Frequency Changer Without Intermediate D-C Step

(a). Flexible or Rigid Direct Coupling of Systems

The converter referred to above could be built up by using either single-anode or multianode tank rectifier and inverter; the one discussed below necessitates the single-anode tank arrangement. Figure 4 shows the basic circuit diagram of such equipment, consisting of a transformer and 12 single-anode grid-controlled rectifier-inverters; one set having their cathodes and the other set their anodes connected to one side of the single-phase system. Each pair of tanks connected to the same secondary winding constitutes a switch, in other words they permit current to flow in either direction. Let us assume that the grids of tubes R_1 permit current to flow while all other anodes are blocked, then the transformer winding 1 is connected to the single-phase system. After a certain period this set of tubes is blocked and set R_2 is released, thus phase 2 of the transformer may supply current. After another period of time the next phase, 3, is brought into play, and then 4, 5, etc. Figure 5 shows the voltage of each phase, and below the arc current which is commutated from each anode to the anode of the succeeding phase as the impressed alternating voltage of this phase becomes more positive than that of the phase carrying the arc. It would have to be arranged, therefore, that the grid-control equipment permits the flow of current according to the time interval t_1 to t_{14}. This results in sections of voltages e_1 to e_6 being made available and joined to the heavy-line curve which becomes the voltage e_s of the single-phase system. The flow of current through the individual tubes can be seen from the second curve of figure 5 for the case where the single-phase voltage and current are in phase.

The frequency ratio between e_1 to e_6 and e_s as shown in figure 5, upper curve, is about 3:1. However, as can be seen from the voltage curves below, any frequency ratio may be obtained, as any number of sections e_1 to e_6, or e_1 to e_6+e_1, or e_1 to $e_6+e_1+e_2$, etc., of the transformer phase voltages can be built up to produce the

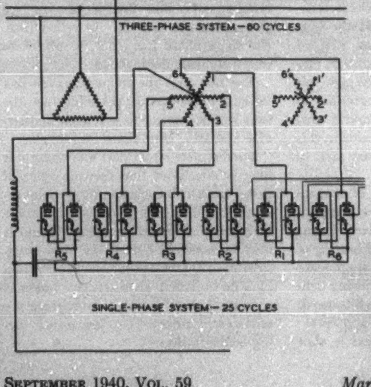

Figure 4 (left). Fundamental circuit diagram of an electronic frequency converter

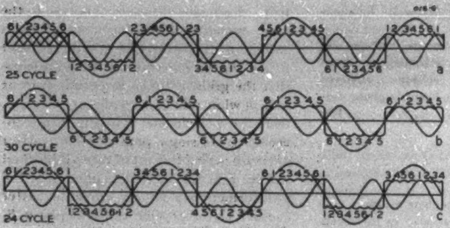

Figure 6. Diagram showing the firing of anodes for various frequency ratios in a flexible frequency converter

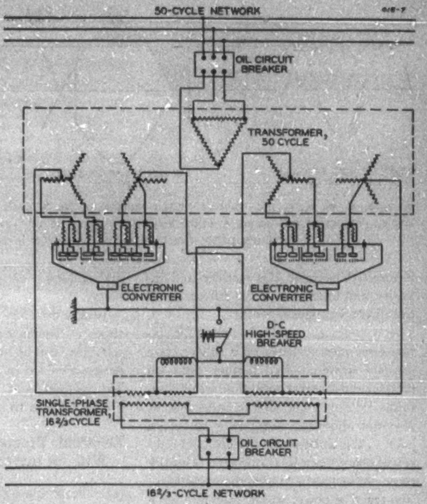

Figure 7. Fundamental circuit diagram for a rigid frequency converter

desired single-phase voltage e_s. A further consideration of these curves will show also that a change in the frequency of the three-phase voltage still permits obtaining a constant single-phase frequency. The flexibility of this type of frequency changer with electronic equipment will be analyzed still further below using figure 6.

As is well known the firing of the anodes can be controlled by means of grids in such rectifier tubes and therefore the voltage curve e_s in figure 5 could be made to resemble more closely a sine wave by retarding or accelerating the firing of some of the anodes.

The scheme[3,4] of employing a transformer with a modified secondary winding (see figure 4, system 1′, 2′, 3′, 4′, 5′, 6′) cannot be used unless the ratio of the frequencies is for instance 3:1, as is the case in Europe between the conventional 50-cycle power and the $16^2/_3$-cycle railway systems. Furthermore, this permits only a rigid coupling between the two systems. For these reasons no further consideration will be given to these methods in this paper.

Analyzing still further the arrangement shown in figure 4 of frequency conversion, it is quite apparent that this type of equipment and others which will be discussed later do provide a completely flexible coupling between two systems. For the sake of brevity no detailed consideration is given in this discussion to the subject of commutation between sections of a rectifier system nor to the influence upon commutation in case a potential is impressed upon the single-phase system by other converters. However, an analysis of conditions caused by various ratios of the three-phase to single-phase frequencies is given below for purpose of determining the duty imposed upon the individual anodes.

Part *a* of figure 6 shows the condition existing when the frequency ratio is 60 to 25. The commutation of current between the two rectifier systems can be effected at any instant by means of the grid-control equipment.

Part *b* illustrates the condition when the frequency ratio is 60 to 30. Here we see that each of the six anodes fires only once during the active period of either system; further, we also see that the same anodes bear the entire burden of each commutation, and each of the others always carried the current during the same part of the active cycle of its system. From this it is obvious that the duty on the anodes within one of the systems cannot be equally distributed, and the anode subjected to the most severe duty will govern the rating of the rectifier.

Part *c* indicates the relationship existing when the frequency ratio is 60 to 24. Conditions in this instance are more favorable than for the ratio of 60 to 30, but it does have some undesirable characteristics. Investigation shows that the burden of commutation is now divided equally among four of the six anodes employed in each system, and although this does limit the capacity of the rectifier to some value less than it would have if used only for rectification, the reduction in this case is less than for the frequency ratio of 60 to 30.

From the above discussion of the unusual frequency ratios it may at first appear that the ratio of 60 to 25 is very near to the undesirable condition of loading of anodes encountered when it approaches 60 to 24. However, before drawing definite conclusions it might be well to recall the reason for developing such apparatus; that the coupling be entirely flexible, that is, that the frequency ratio may be a variable. With this in mind let us consider what determines the frequency of the two systems; in the case of the three-phase system it is without exception dependent upon the speed of the prime movers driving the generators, while the single-phase system may or may not include rotating equipment. The three-phase systems are well known to maintain a constant frequency; on the other hand, traction systems do allow relatively large variations, the reason being that if compared to the supply capacity, great power demand fluctuation occurs. In the case where no rotating equipment is supplying energy to the single-phase system, its frequency will be a function not only of the active power requirements, but also of the reactive power demand as well. In either case, the single-phase frequency is subject to relatively wide fluctuations.

The fact that the frequency ratio is a variable eliminates the possibility that the unit will be subject to sustained undesirable operating conditions.

Furthermore, from part *b* of figure 6 it may be concluded that the conversion of power from a 50-cycle to a $16^2/_3$-cycle system (3:1) does not provide a favorable utilization of the rectifier-inverter and it may be concluded from the above consideration that more favorable operation may be obtained when 60-cycle power is converted into 25-cycle power, since the anodes are subjected to a lower duty during commutation.

(b). RIGID INDIRECT COUPLING OF SYSTEMS

Figure 7 shows the diagram of connections of such a type of frequency changer with the electronic converters and the three-phase and single-phase transformers. This system has, however, a serious inherent disadvantage—namely, the coupling is not flexible and therefore any change in frequency on one system will automatically affect the frequency of the other. However, in spite of this drawback such equipment has been installed to supply a small railroad with $16^{2}/_{3}$-cycle current. The set is rated 3,600 kva continuous load, 2,520 kw (power factor 0.7) 4,000 kva one-half hour, and 6,000 kva, one minute, and has been in commercial operation since December 1936. The unit furnished the entire load for over a year for this branch railroad which was up to then supplied by means of two motor generator sets, each rated 2,100 kva. Therefore, these two motor generator sets were used only for standby units, but it was contemplated to have one working in parallel with the static frequency changer as soon as this method of conversion has proved satisfactory and could then be reconnected in such a way that it could work in parallel with any other converter, whether of the mechanical or another electronic type. The original setup as indicated above was such that the frequency of the single-phase output was a function of the frequency of the three-phase supply system. In other words, the coupling of this system as originally used was not flexible and parallel operation of different units could not be accomplished without using a connection similar to the one which will be explained below. The frequency changer was supplied by a 45-kv 50-cycle transmission line, and therefore the rectifier transformer was provided with a 45-kv delta primary winding. The voltage of the intermediate d-c system of the frequency changer was chosen at 2,000 volts and does not depend upon the voltage of either the three-phase or the single-phase network.[8,17,18,19,20]

The grid control of this unit is such that a slight inaccuracy in the adjustment of the firing period may make the unit completely inoperative. Furthermore, this method of frequency changing is very limited, as stated before, as it does not provide a flexible coupling, produces an unequal loading of the anodes, and necessitates a tank with an abnormal number of anodes. The advantages which may be stressed are long firing time of the anodes, and the possibility of furnishing wattless power from one network to the other.

Two things, however, were definitely demonstrated by the installation of this type of static frequency changer, namely, that it requires less space and has less weight, both of which reduce the cost of the building and foundations. Furthermore, the efficiency at light load was considerably higher than the one which could be obtained with a mechanical converter.

It may be mentioned that right from the beginning considerable difficulties were experienced due to the fact that the communication systems were exposed to the trolley, as well as feeder system, both of which showed considerable current and voltage wave distortion from the rectifier-inverter. This situation was corrected by means of filters. Further on will be outlined some schemes and methods which may be employed in order that the inductive co-ordination of power and telephone systems may be obtained for large installations of static frequency changers without using filters.

(c). FLEXIBLE INDIRECT COUPLING BETWEEN SYSTEMS

The static frequency changer discussed below has recently been perfected and is based on a somewhat different principle than the arrangements described above. It attracted considerable attention among European engineers, especially due to the fact that it permits flexible coupling of two a-c systems of any frequency, without appreciable distortion of the current and voltage waves. Such a frequency changer was recently put in commercial operation for coupling an a-c three-phase 50-cycle system with a single-phase $16^{2}/_{3}$-cycle trolley system, converting as much as 3,000 kw. A similar electronic converter has been placed in operation, of a capacity of 1,600 kw, coupling a 50-cycle three-phase system with another three-phase system which has a frequency of 42 cycles. Both installations have already given several thousand hours of satisfactory service.[8,10,24]

Figure 8. Simplified circuit diagram for demonstrating flexibility of electronic frequency converter

Let us therefore describe this system more fully by means of a simplified circuit, figure 8. This circuit may have no practical value, but will permit ready analysis of all the phenomena with which we shall be concerned.

The scheme represented in figure 8 comprises two a-c synchronous generators, G_1 and G_2, feeding a two-winding d-c motor (M) through a connection without appreciable resistance and through rectifier tubes R_1, R_2, each tube being equipped with control grids. Neglecting the voltage drop in the connections and in the rectifier, the generator, let us say, induces a voltage E somewhat higher than the back electromotive force of the motor. Energy will then flow from the generator to the motor if the grids are energized so that the anodes of the rectifiers are permitted to carry current. Let us assume that one electric valve, R_2, is blocked and therefore current will flow only through the left-hand winding of the motor, bringing it up to speed in the direction indicated by the heavy arrow. The motor will operate in this direction as long as current I_1 produced by generator G_1 can flow through R_1. At a certain instant of time the grids of rectifier valve R_1 are negatively energized by the auxiliary grid equipment, current I_1 is prevented from flowing, and the motor comes to a stop, see figure 8. However, at the same time the grids of R_2 are de-energized and since generator G_2 impresses a potential E_2, current I_2 will flow through the right-hand winding of motor M and bring this motor up to speed; however, in the opposite direction. It can therefore be seen that by impressing a negative potential on grids of rectifier R_1 and then on grids of rectifier R_2, this motor will reverse at a frequency equal to the frequency of the voltage applied to the grids of these two rectifier valves. The frequency of the reversal of motor M is independent of the frequency of generators G_1 and G_2—in other words, independent of the frequency of the voltage applied to the anodes of rectifiers R_1 and R_2. Further, it can be seen that the frequency of reversal of motor M is independent of the frequencies of generators G_1 and G_2 whether these generator frequencies are the same or not.

Let us now apply the above reasoning by following the circuit of figure 9, and we shall find that with a simple control device for energizing the grids, power of a 60-cycle frequency can be converted into single-phase energy of 25-cycle frequency if the grids of the anodes of the left-hand unit and those of the right-hand unit are energized consecutively with potentials of opposite polarity. The reversal frequency of the grid potentials would have to be equal to the frequency of the single-phase output, namely, 25 cycles. In this arrangement, however, instead of a reversal of direction of rotation, a reversal of voltage on the primary of the single-phase transformer takes place, which is at the rate of 25 cycles if the grids are controlled from the single-phase 25-cycle network.

A more specific arrangement of the grid control is shown on the left-hand side of figure 9. The potential of the grids is controlled by three mechanical contacting devices m, m_1, and m_2, and is supplied by a battery. The devices m_1 and m_2 which are driven in synchronism with the frequency of the three-phase system therefore energize the grids at the same frequency as the anodes of each group, S_1 and S_2, of the rectifier-inverter. However, contactor m supplies the battery potential to each of the contactors m_1 and m_2, or, in turn, to each group of anodes S_1 and S_2, according to the speed of motor M_2. This motor, as can be seen, is driven from the 25-cycle system and, if of the synchronous type, will energize the grids of each group negatively through the battery and contactor segment m once during each revolution or, if a two-pole motor is used, at the frequency of 25 cycles. If the frequency of the single-phase system changes, then the speed of rotation of contactor m changes, and accordingly the interval during which the brush is in contact with the segment. The groups S_1 and S_2 may therefore furnish current for shorter or longer intervals which will be reflected in the frequency of the energy transferred to the single-phase system. Therefore, the frequency of the energy transferred to the primary winding of the single-phase transformer from the three-phase network follows the frequency of the impulses of the contactor m, and since this device is driven by a synchronous motor M_2, energized by the single-phase system, it follows the frequency changes of this system. A completely flexible coupling of the two systems is therefore effected.

The same results can be obtained by using electronic instead of mechanical control equipment, see figure 10. Comparing this with the mechanical control shown in figure 9, the circuit of the electronic control can easily be analyzed. A 12-anode rectifier with electrically controlled grids is connected to the secondary windings of a 60-cycle transformer. The energy-storing equipment comprises a reactor and a battery of capacitors. The control devices consist of grid-controlled tubes and 60- and 25-cycle auxiliary transformers.

Relative Advantages and Disadvantages of Different Methods of Frequency Changing

The discussion below will deal especially with the system shown in figure 10, or similar ones, and only touch lightly on other methods of frequency changing.

From the foregoing it could be seen that the system as shown in figure 2 with an intermediate d-c step does not make it possible for the three-phase network to take care of the reactive power of the single-phase trolley system. Synchronous or static condensers would have to be connected to the trolley system, see figure 2, or then the reactive power would have to be furnished by rotating converters connected in parallel with the electronic converters. Furthermore, in order to obtain successful operation, a reactor has to be connected into the d-c link for reasons given in the second section of this paper. This method, however, permits transferring energy in either direction and may show some additional advantages after more experience has been obtained with d-c transmission of power. Furthermore, this method provides a completely flexible link between the two systems, has a high conversion efficiency (since a high intermediate direct voltage can be chosen making the arc losses negligible), and possesses effective regulation and protective features by means of energized grids.

Such systems for conversion of three-phase power into direct current and back into another three-phase system have been operating in the United States and Europe for many years. These systems make use of intermediate direct voltages of 3,000, 15,000, and up to 48,000 volts, respectively.[11,21,22,27] Although these systems are three-phase to three-phase conversions, still they deserve careful study when considering new frequency-changing equipment for railroad electrification.

Figure 9. Circuit diagram of electronic frequency converter showing mechanical grid-control equipment

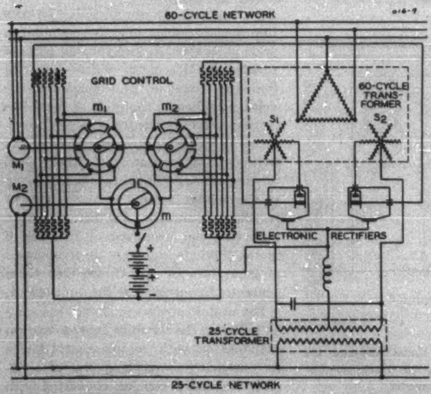

Figure 10. Circuit diagram of electronic frequency converter showing static electronic grid-control equipment

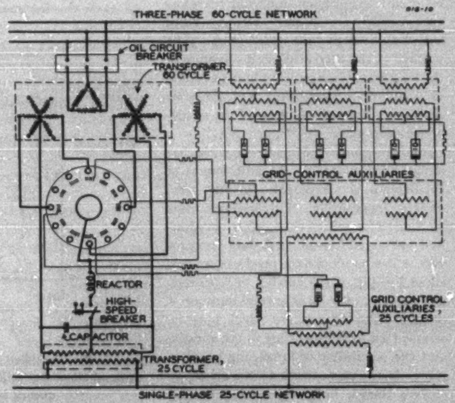

The direct-coupled system (no intermediate step), although it can be made flexible, did not receive much attention in the initial tests nor was such equipment installed on some of the European railway systems. The output voltage for the rectifiers is determined by the trolley voltage and will therefore be fairly high for all existing electrified $16^2/_3$- or 25-cycle lines, and the anodes of this rectifier as well as of the inverter are subjected to a high commutation voltage.

The indirect-coupled systems permit the selection of the most suitable rectifier-inverter voltage in order to utilize the anodes to the fullest degree as the single-phase transformer ratio can be chosen accordingly. Both methods, shown in figures 7 and 10, have been utilized and are therefore given further consideration below. The investigations were made based on a set for 5,000 kw, a power factor of 70 per cent, and conversion of power from 60 to 25 cycles at conventional alternating voltages. The rating of 5,000 kw for the electronic converter sets was chosen in order to be in line with the rating of the present single-phase feeder transformers as used on one of the main electrified lines. Both sets are static and permit the same ease of starting, and may therefore be applied in the same way in connection with electrified lines.

The rectifier-inverter tanks consist of several anodes equipped with energized grids and their necessary control devices. The first method of this kind, see figure 7, necessitates an abnormal number of anodes per tank and an exceedingly accurate control device. Furthermore, the transformer connections are quite abnormal and require a relatively complicated design. The other indirect-coupled system makes use of normal rectifier-inverter tanks with grids, a 60-cycle three-phase transformer with double six-phase secondary, and interphase transformers, both being of the same types as used in standard rectifier installations, and a 25-cycle transformer, single-phase with mid tap.

It can therefore be realized that this last-mentioned system deserves careful consideration. However, some of the main characteristics of both these indirect-coupled systems will be discussed below. Since most of these systems are flexible they have to be compared with motor generator sets which permit elastic coupling of two networks.

Voltage Regulation

From figure 11*a* it can be seen that the voltage regulation is similar to the regulation of a standard transformer. Curve 3 shows the regulation of a transformer, and curve 1 that of a 5,000-kw frequency changer, while curve 2 gives the voltage regulation of a motor generator set. It may be pointed out, however, that should this voltage drop, of about seven per cent at full load, be objectionable, a curve similar to number 2 could be obtained by means of additional grid-control devices, as shown in figure 10. This voltage regulation is naturally due to the drop in both of the transformers, in the reactors, and the arc drop of the rectifier-inverter. As pointed out above, the voltage of the intermediate system can be chosen independently of the voltage of the a-c systems, and therefore if chosen at 2,500 volts, for instance, the regulation due to the rectifier-inverter arc drop would only amount to about one per cent at 5,000-kw load.

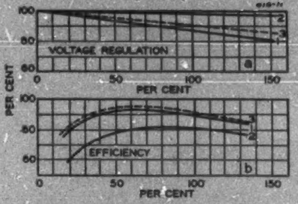

Figure 11. Performance characteristics of a typical electronic frequency converter of 5,000-kw rating compared with a transformer and flexible rotating converter of equal rating

It may be pointed out that the voltage regulation of such a frequency changer is not affected by fluctuations of frequency nor by the phase relation between the voltages of the two networks, as is the case, for instance, in a synchronous motor generator set.

Efficiency

Not only is the efficiency of such a set higher at full load compared to a motor generator set, but it becomes relatively higher at lower loads. From figure 11*b* the efficiency of such a unit, curve 1, can be compared with the efficiency of a motor generator set, curve 2, as well as with that of a transformer, curve 3. The arc drop of the rectifier-inverter is very low and therefore the efficiency of such a frequency changer is also practically the same as that of a transformer, which can couple two networks of different voltages, but naturally cannot couple two networks of different frequencies.

It may be mentioned here that efficiency measurements on some of the actual installations to which reference was made previously reached as high as 93 per cent at full load. Curve 2 refers to a motor generator set of a design which permits flexible coupling of the two systems.

Due to the fact that in the installations referred to above the load factor is relatively low, about 25 per cent, the average difference in efficiencies between the motor generator set and the rectifier-inverter amounts to about 15 per cent. In other words, the losses are reduced very appreciably by this new type of converter. This, as pointed out above, is mostly due to the fact that the efficiency of such a type of frequency changer maintains a very high value, even at low loads.

Power Factor

A certain amount of wattless power has to be supplied by an external source to a frequency changer of the electronic type. This is required for the magnetization of the transformers and partly also on account of the phase displacement existing between the voltage and the current in this type of equipment, especially if grid voltage control is employed. In case of a system as shown in figure 7, if the energy-storing equipment is omitted, the power factor would probably only amount to about 60 per cent. In other words, a very high component of wattless energy would have to be furnished from the a-c supply system. However, with an arrangement such as shown in figure 10, a power factor of as high as 95 per cent can be obtained. Analysis shows that economically it will be feasible to equip such a set with an energy-storing equipment. However, it may be pointed out that in case the capacitors should fail for any reason, the frequency changer would not be affected in its operation. However, it would then adversely affect the three-phase system, by drawing additional wattless power, and causing an unbalance of the three-phase system.

Protective Equipment

In all considerations referred to above, reference was made repeatedly to grid-control equipment in connection with regulating the valve action of the rectifier and inverter, as well as regulating the voltage. It may be pointed out, however, that the grids may be used for another purpose also, namely, to protect the equipment in case of abnormal operating conditions and disturbances on the line as well as short circuits and backfires.[28] Extensive tests in many installations have proved that the electrically energized grids are able to interrupt the current flow in a tank such as proposed for the above frequency-changer set. The equipment required for this purpose consists of relatively inexpensive devices which permit energizing the grids of the inverter with a negative potential in case of sudden disturbances. Recent tests have shown that this time can be confined to less than one-sixth of a cycle. Naturally this equipment will not eliminate breakers completely but may make it possible to use switching devices of lower rating.

FEEDER AND TROLLEY VOLTAGES

It can easily be realized that since any ratio between primary and secondary voltage on both transformers can be chosen, no additional equipment will be necessary in case the single-phase 25-cycle system would require a higher voltage than commonly used. In the case of a motor generator set, it would probably not be advisable to generate directly a voltage of 25,000 volts or higher, but instead a transformer could advantageously be connected between the single-phase generator and the trolley system.

SPACE REQUIREMENTS

Present installations have shown that a considerable saving in space can be obtained with this type of frequency changer. Furthermore, the cost of foundations and building can be greatly reduced, similarly as in any mercury-arc-rectifier installation.

FLEXIBILITY OF A STATIC FREQUENCY-CHANGER SET

As pointed out repeatedly, a set as shown in figure 10 can operate without losing its stability even in case of severe frequency variations on either of the two systems, or during heavy load swings.

TELEPHONE INTERFERENCE

As mentioned in the introduction, the installation of one of these frequency changers caused relatively serious disturbances in the adjacent telephone lines. However, it must be realized that this installation was fed from a relatively small power source, and therefore the wave-shape distortions due to the rectifiers were transferred to the a-c networks without appreciable diminution. For large railway systems, where many units would be used, it may be possible to take care of this situation by establishing such phase relations between the different units that a multiple-phase system could be obtained, as was done in one of the largest rectifier plants recently installed in this country.[23]

Conclusion

It can thus be seen that there are several methods which permit coupling of networks of different frequencies with static electronic devices. The first system, using an intermediate d-c step, has a considerable drawback in that no wattless power can be transmitted from one system to another. However, it has proved very successful for coupling three-phase networks.

The direct-coupled system, although it does not have the above-mentioned disadvantage, necessitates that the output voltage of the rectifier-inverter be equal to the single-phase voltage and requires that single-anode rectifiers be used.

The indirect-coupled system, on the other hand, permits choosing any output voltage for the rectifier-inverter, allows the exchange of wattless power from one system to another, and permits full flexible coupling. The methods used in Europe, necessitate a 3:1 ratio between frequencies, and cannot be applied to the electrified railway systems in the United States where frequency conversion from 60 to 25 cycles, or a 2.4:1 ratio is necessary. However, the conversion of frequencies, as is necessary in this country, may subject the anodes of the rectifier-inverter to a more favorable load cycle than in case of the frequency ratios required in Europe.

In order to give a proper comparison between the characteristics of these converters of the electronic type with those of the rotating converters at present used, a rating of 5,000 kw was selected for ready reference.

It could be seen from the foregoing that the main advantages of an electronic frequency changer are high efficiency, very simple operation, no necessity for special starting equipment or high starting load, instantaneous starting up of the equipment, small weight of the equipment, especially of the control equipment, which reduces costs for housing and foundation.

The disadvantage of such converters, in so far as can be seen at present, is the distortion caused by them on the three-phase supply network, unless somewhat large and costly energy-storing devices are employed.

It may also be pointed out that the present installations referred to should make it possible to develop in the future frequency changers of this type for very large capacities which may also become a very useful means for the conversion of power for present electrified systems now using 60-to-25-cycle motor-generator converters.

Circuit Interruption by Air Blast

W. S. EDSALL
MEMBER AIEE

S. R. STUBBS
ASSOCIATE AIEE

Synopsis: By using the prestored energy of compressed air for the twofold function of circuit interruption and circuit-breaker operation, a new and original oilless circuit interrupter has been evolved. This air-blast circuit breaker has a guillotine-like arc-interrupting characteristic and can be made practically immune to the adverse effects of circuit recovery voltage.

The historical background of oilless circuit breakers is discussed with particular reference to European designs. The electrical and mechanical design of air-blast circuit breakers for indoor use and the factors affecting that design, are described in some detail.

IN VIEW of the desire to eliminate oil in electrical apparatus evidenced by the electrical power industry, research activities conducted during the past decade have been directed toward the development of a satisfactory current-interrupting principle, not involving the use of oil, but capable of application over the same ranges of current, voltage, and interrupting-capacity steps as the oil circuit breaker.

Fundamental Requirements

It has been recognized that to be acceptable to American power engineers, it is essential that any oilless circuit breaker must be compact, simple in operation, reliable, economical, and easily adaptable to the various forms of circuit connection and mounting at present obtaining for the oil circuit breaker. In addition, the desirability of obtaining an increase in interrupting efficiency has been recognized.

Development of Air-Blast Breaker

It is economically advisable and expedient that American manufacturers should avail themselves wherever possible of the operating experience and evolutionary test data appertaining to successful European designs, for, by so doing, much development time and expense can be eliminated, resulting in ultimate savings to the user. This procedure has been followed in the case of the air-blast breaker here described, thereby resulting in an initial American design from which outstanding reliability of operation has been obtained. A typical indoor air-blast circuit breaker of American manufacture is shown in figure 1.

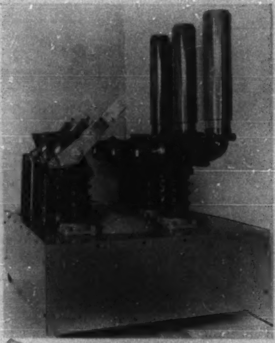

Figure 1. Type AB indoor air-blast circuit breaker, 1,200 amperes, 15,000 volts, 500,000-kva interrupting capacity having active operating parts enclosed

European air-blast circuit breakers, of both axial and cross-blast designs, have been found to be subject to certain limitations so far as their ability to interrupt high currents is concerned. In addition, these limitations are aggravated when high rates of recovery voltage obtain.

In view of the mechanical advantages and operating experience of a certain European design, it was thought desirable to so improve the design of the interrupting chamber as to increase the maximum interrupting current ability of the breaker to the point where it would be adequate for use on American power systems. To this end, considerable laboratory research was conducted.

In the typical European type of axial air-blast breaker interrupting chamber, the compressed air approaches an orifice through a converging port, and exhausts through a diverging throat. In many European designs, too, the interrupting contact is a part of the isolating contact. This arrangement makes for inefficiency of the interrupting air blast as will be shown later in the paper.

As the result of extensive research, it was found that the arrangement of interrupting chamber shown in figure 2 has a greater interrupting efficiency, particularly at high currents, than the European type of converging-diverging chamber.

It will be noted from figure 2 that the American development incorporates a structure having parallel walls. Redesign of the cooling chamber to obtain increased air velocity, and the introduction of concentric metallic cylinders within the arcing chamber, produced further improvement. Main current-carrying contacts, as distinct from the arcing contacts, were also added.

Operating Characteristics

The design here described capitalizes on the mechanical operating experience and reliability of the European design and, using the prestored energy of compressed air for both circuit-breaker operation and circuit interruption, produces a practically constant circuit-interrupting characteristic, with the result that arcing times of one-half cycle or less are consistently produced throughout the interrupting range of any particular breaker, as shown in figure 3. The typical interrupting test oscillogram, shown in figure 4, shows the short arcing time obtained with this design.

As a consequence of the short arcing time, contact burning is very low and many repetitive operations can be made without contact renewal.

Discussion

Discussion will be found in the 1940 annual Transactions volume and in the 1940 "Transactions Supplement" to Electrical Engineering.

It has also been found that the interrupting action can be so controlled as to be independent of system characteristics, since it is possible to control the rate of rise of recovery voltage across the interrupting contacts immediately following arc interruption by means of the automatic insertion of resistors which prevent the occurrence of high-frequency transients and reduce the instantaneous values of generator electromotive force appearing at the moment of arc interruption.

Axial-Blast Application

Tests have proved that when using an axial-blast form of interrupting chamber, there is an optimum distance of break between the arcing contacts which produces a maximum interrupting effect. Figure 5 shows the relationship between megavolt-amperes interrupted and arcing-contact separation, with air pressure and port area constant. Obviously, it is desirable that in any air-blast circuit-breaker design, the arcing contact separation should be that which provides maximum interrupting efficiency.

Separation of Interrupting and Isolating Functions

It is evident that, since in indoor air-blast circuit breakers the maximum interrupting efficiency is achieved with a short arcing-contact separation of only one-half inch, considerations of circuit isolation require a co-operating disconnecting means. This necessitates an initial arcing contact break sufficient for the maximum interrupting efficiency, immediately followed by an appropriate isolation break, in series, opening under no-load conditions.

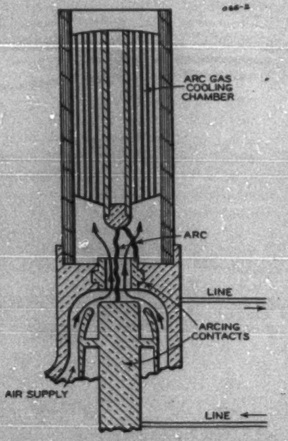

Figure 2. Typical air-blast interrupting chamber—American design

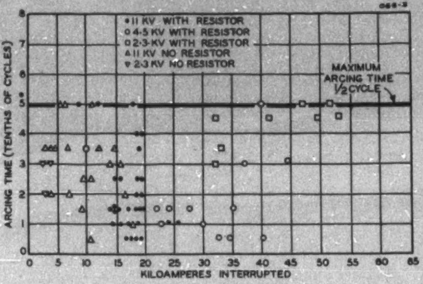

Figure 3. Graphical representation of interrupting-test data showing arcing time in tenths of cycles

The use of an independent interrupting contact also permits a very speedy opening of the arcing contacts during interruption, since the inertia of these contacts is relatively negligible when compared with the energy available in the compressed air. The isolating means takes the form of a disconnect switch, and is operated by the same pneumatic energy that opens the interrupting contacts and interrupts the circuit.

Compressed air used for operation of the contacts constitutes a pneumatic co-ordinating device which acts as a positively functioning mechanical interlock of unlimited flexibility. The relative diameter and volume of the operating devices, and of the air ducts leading to them, provide a superior timing means with which to insure proper sequential operation.

Closing Capabilities

Completion of the circuit through the breaker during closing, is achieved by means of the closing of the disconnecting or isolating contacts only, since, except during the interrupting process, the arcing contacts are held closed by the action of heavy springs.

Actual contact, during closing, is made between the movable disconnecting or isolating blade contact and a laminated wedge-type stationary contact. Burning, during closing, is very slight. Even when closing against currents of 140,000 rms amperes and above, there were only slight evidences of scorching or pitting.

The reason for the low contact-burning characteristics of the air-blast breaker during closing is in the very high speed of closing obtained. In order to burn a given quantity of contact material a definite amount of energy is required. Since time is a factor in the energy equation, and since, due to the high closing speed, the period of arcing during closing is extremely short, the breaker can be closed against very high currents without appreciable damaging effects, and with practically no heating or pitting of the contacts. It is especially to be noted that no blast of air on the contacts is required during the closing operation.

Separation of the interrupting and closing functions between two sets of contacts divides the contact deterioration consequent upon these functions; thereby lengthening the over-all contact life of the breaker.

Trip-Free Interrupting Contacts

As in the air-blast breaker the interrupting contact is free to move independently of, but co-operatively with the isolating or disconnecting means, it is essentially trip free in its position and relation to the disconnecting contacts. This fact is of great advantage, especially in the higher-voltage outdoor breakers where extremely rapid interrupting and reclosing times are required.

Breaker Arrangement

A typical design of indoor air-blast breaker is illustrated in figures 6 and 7. A compressed air tank (1), fitted with a main air blast valve (2), forms the foundation on which the active parts of the breaker are mounted. The arcing chambers (3) and disconnect movable members (5) are supported by hollow insulator columns attached to the tank assembly. The arcing chambers exhaust into cylindrical mufflers. Operation of the disconnects is achieved through insulated link (6) and shaft (7), connected to air pistons (8) and (9). Valves (10) and (11) control the air supply.

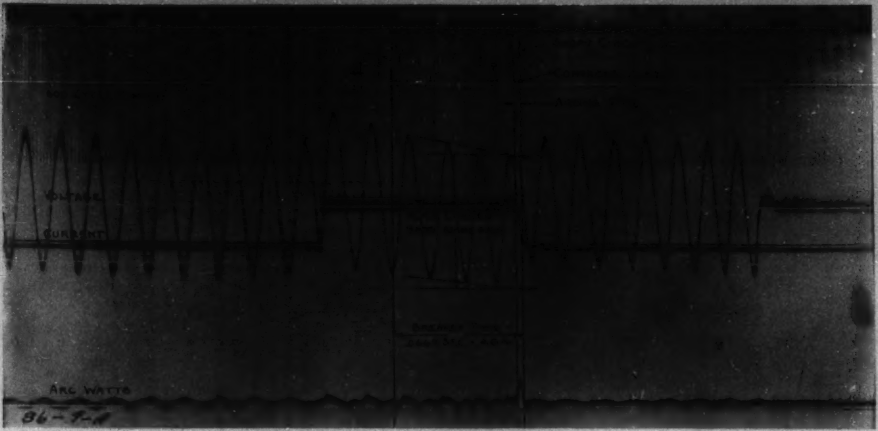

Figure 4. Type AB air-blast-circuit-breaker interrupting-test oscillogram

CO operation at 192,000 kva at 11 kv interrupted by a breaker having a 250,000-kva interrupting rating

Operation

Opening

When opening, electrical or manual actuation of control valve (11) results in opening of the air-blast valve (2), admitting air at 135 pounds or 215 pounds per square inch gauge pressure into the interrupting chambers.

Movable arcing contact (14), normally held closed by the action of heavy springs, is attached to a piston. As air pressure builds up within the interrupting chamber, the piston is depressed, withdrawing contact (14) the required distance away from the stationary arcing contact and air-blast orifice (13), drawing an arc between the contacts. As the tubular stationary contact is the only outlet for the compressed air, a blast of high-velocity air is simultaneously impelled across the initial arcing zone, resulting in limitation of arc-energy release and preventing reignition after the first current zero.

Simultaneously with the admission of air to the interrupting chamber, air pressure is applied to piston (9) resulting in opening of the disconnect contacts (5), under no load, as soon as arc interruption is complete.

Immediately the disconnecting contacts open, an auxiliary contact interrupts the circuit to valve (11), closing the valve. This cuts off the air supply to valve (2) and permits the air remaining on the reverse side of this valve to escape. The main valve then closes under the influence of a heavy spring and the pressure of air remaining in the tank; pressure in the arcing chamber falls and results in reclosing of the arcing contact due to spring pressure.

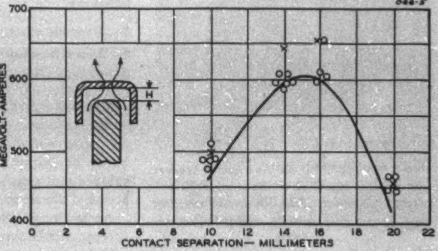
The air required for arc interruption causes pressure in the breaker air tank to fall. Since the tank is permanently connected to a compressed air storage system, the supply of air within the tank is quickly replenished.

Closing

When closing, electrical or manual actuation of control valve (10) causes compressed air to be admitted to the closing cylinder (8), resulting in the closing of the disconnecting switches. As the arcing contacts are already held closed, the closing of the disconnecting switches completes the circuit.

Figure 5. Relation between interrupting-contact separation and interrupting ability in megavolt-amperes

Circles—Effective interruption
Crosses—Interruption with remnant arc
(Air pressure and port area constant)



A simple mechanical interlock insures that all switching operations, once initiated, will be carried to completion. A mechanical trip-free device permits immediate reopening of the disconnecting switches in the event of their being closed against short circuits, even though air pressure may still be exerted upon closing piston (8).

Reliability of Operation

The successful air-blast breaker has to be more than an interrupting device. It must have adequate insulation, and must be able to carry its rated current continuously without exceeding prescribed temperature limitations. Also, like all circuit breakers, it must be capable of operating many times a day without failure of mechanical parts, and yet, on the other hand, be capable of operating satisfactorily after having stood for a period of time without being operated. Several years of experience in the manufacture and operation of air-blast circuit breakers have provided knowledge of the proper materials to use in mechanical parts, such as pistons, valves, valve seats, piping, and interlocks; giving assurance that the breaker can accomplish repetitive operations, as well as function satisfactorily, when infrequently operated.

Apart from the two solenoid control valves for closing and tripping the breakers, there is only one valve which must seal against the air pressure. This is the main air-blast valve, which is a simple composition valve, easily accessible. The method of mounting this main air-blast valve is such that the air pressure in the storage tank acts on the valve to secure tightness.

General Factors Affecting Design

The most efficient circuit breaker is the one in which, all other things being equal, the rate of dielectric recovery between the arcing contacts, immediately following the first passage of the current wave through zero, after parting of the contacts, is always greater than the rate of recovery voltage rise across the contacts. Under these circumstances, restriking of the arc is impossible and the maximum period of arcing is one-half cycle.

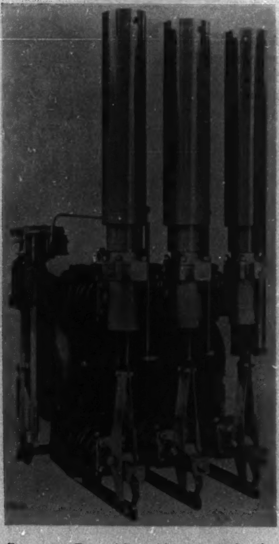


Figure 6. Type AB air-blast circuit breaker with vertical mounting arrangement, 600 amperes, 15,000 volts, 500,000-kva interrupting capacity—equipped with arc-paralleling resistors

In designing a circuit breaker, there are two lines of attack by which maximum interrupting efficiency may be obtained. First, by the production of a high rate of dielectric recovery and second, by limiting the rate of rise of the recovery voltage. These two factors are used in the design of air-blast circuit breakers with such marked success as consistently to produce arcing times of one-half cycle or less.

Tests have proved that there are four factors which influence the interrupting capacity of high-voltage air-blast circuit breakers. These are:

1. Air pressure
2. Port area
3. Series breaks
4. Automatic insertion of resistors

The first three of these factors contribute toward control of dielectric recovery. The fourth factor produces a measure of control over the rate of rise of recovery voltage. The proper correlation of such of these factors as may be required produces air-blast circuit breakers of almost any desired interrupting capacity in the sizes usually required. This holds true for a wide range of interrupting capacities and for all standard voltage ratings up to and including 220,000 volts.

Factors Affecting Dielectric Recovery

AIR PRESSURE

Dielectric recovery between the arcing contacts of air blast breakers is assisted by three different air-pressure characteristics. These characteristics result in the following:

1. Dynamic effect
2. Dielectric effect
3. Cooling effect

Dynamic Effect. Initial opening of the arcing contacts is effected by means of the air pressure itself. An arc is drawn between the contacts, but is immediately enveloped and centralized by the dynamic action of the air under high pressure.

An arc may be visualized as an incandescent core of concentrated electrons surrounded by an incandescent envelope of ionized gas. Due to the dynamic effect of the compressed air, the arc is centralized and its length controlled. This contributes toward limitation of arc energy release.

During the process of arc extinction the air pressure rapidly forces the arc products and any ionized gas into an arc gas cooling chamber, and so produces extremely rapid scavenging and deionization of the arc path.

Dielectric Effect. That the dielectric value of air increases due to compression, is well known. When under a pressure of about 135 pounds per square inch, the dielectric value of air is approximately equivalent to that of high-grade oil. Due to the passage of this high-dielectric medium between the contacts an inherently rapid build-up of dielectric is obtained.

Cooling Effect. The compressed air usually employed, is under a pressure of either 135 pounds or 200 pounds gauge per square inch. It is obvious that the sudden release of such pressures in the arc zone, and the instantaneous expansion of the air, will create intense cooling action. The cooling action deionizes the arc and limits its conducting ability by reducing its cross section.

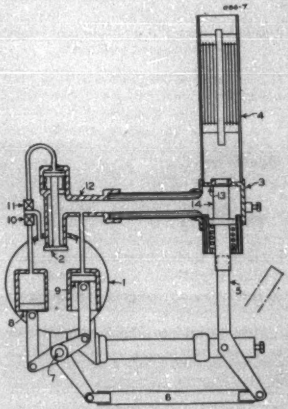

Figure 7. Typical type AB air-blast-circuit-breaker pole section

Due to the inherent characteristics of an a-c system, the cross section of the arc diminishes as the current approaches zero. This causes an increase in the relative cooling effect of the air blast immediately before current zero.

Total Effect of Air Pressure. The combination of a high-velocity high-dielectric cooling medium produces the maximum interrupting effect and is responsible for the short interrupting time of one-half cycle or less, experienced with most air-blast breakers.

Due to the short arcing time, and the low release of arc energy, contact burning is greatly reduced. Consequently, long contact life is obtained, even when interrupting high currents. Many thousands of interruptions are obtainable without the necessity of contact renewal.

Many interrupting tests with varying short-circuit currents, and at different air pressures, have proved that a definite relation exists between interrupting capacity and air pressure. As shown in figure 8, the increase in interrupting capacity is almost proportional to the increase in pressure.

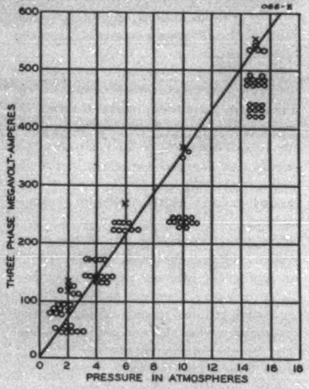

Figure 8. Relation between air pressure and interrupting ability in megavolt-amperes

Circles—Effective operations
Crosses—Ineffective operations
(Port area constant)

PORT AREA

Since a definite control is obtained by means of the dynamic, dielectric, and cooling effects of the air blast, it follows that these effects will be increased if the volume of air made available is increased, provided that the air pressure remains constant.

By increasing the area of the port, increased interrupting capacity is obtained as shown in figure 9. The proportional relationship between the area of the port and the interrupting capacity there shown has been verified by a large number of tests.

SERIES BREAKS

As the recovery of dielectric between the arcing contacts depends more or less directly on the pressure of the air, it follows that, provided air pressure remains constant, an increased measure of dielectric recovery should be obtainable by connecting a number of breaks in series.

Tests have proved that while an improvement in interrupting capacity can be obtained by the use of series breaks, the increase in capacity is not in direct proportion to the increase in the number of breaks as is shown in figure 10.

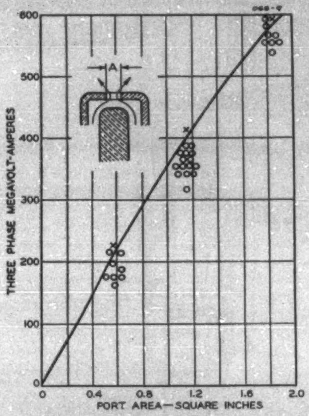

Figure 9. Relation between port area (orifice) and interrupting ability in megavolt-amperes

Circles—Effective operations
Crosses—Ineffective operations
(Air pressure constant)

There are practical limitations to the use of series breaks. Mechanical design factors, insulation difficulties, and costs increase with each additional break. It is also obvious that the expenditure of air must increase with each additional break.

The electrostatic relations which cause unequal voltage distribution across series breaks, increase with the number of breaks. In the case of the indoor air-blast breakers here described, one break per phase is sufficient in all cases.

Factors Affecting Rate of Rise of Recovery Voltage

INSERTION OF RESISTORS

On circuits where the impedance consists largely of reactance, the power factor at the moment of arc interruption may be low. Due to the lower power factor, current zero occurs at a time when the generator electromotive force would normally be in the vicinity of its crest value, so that, at the moment of interruption, the voltage across the contacts rises rapidly to a value corresponding to the generator electromotive force.

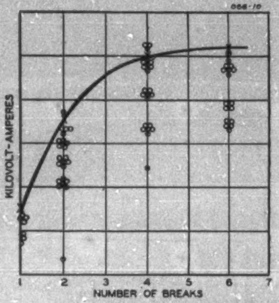

Figure 10. Relation between number of breaks in series and kilovolt-amperes interrupted

Circles—Effective operations
Crosses—Ineffective operations
(Air pressure and port area constant)

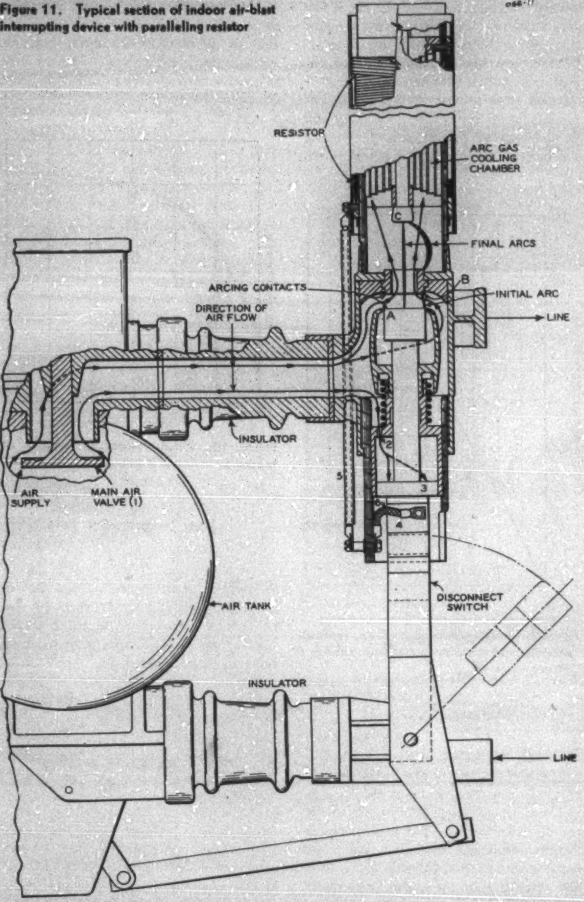
The rate at which the voltage rises is affected by the characteristics of the circuit under interruption, and also is dependent upon the instantaneous value of the generator electromotive force at current zero.

Upon interruption of the short circuit, the stored energy in the system tends to discharge, since a-c circuits are composed of both inductance and capacitance. The well-known inductive kick from coils of many turns, such as field coils, illustrates one type of circuit discharge. The snapping discharge of a capacitor illustrates another. An interruption on a large power system may produce both of these kicks in magnified form, and in an infinite variety of phase relations.

When the generator electromotive force re-establishes itself, immediately upon interruption of the short circuit, the inductive and capacitive discharge effects are superimposed upon the characteristic form of the normal-frequency electromotive force in the form of a high-frequency transient which may rise to a value as much as twice or more the instantaneous value of the generator electromotive force. This transient is usually a combination of various frequencies which depend upon the natural frequency of different circuit combinations obtainable in the system interrupted.

The rate of rise of the combined recov-

Figure 11. Typical section of indoor air-blast interrupting device with paralleling resistor



ery voltage depends upon the instantaneous value of the generator electromotive force, the amplitude of the superimposed transient, and upon the frequency of the transient.

It has long been known that the rate of rise of recovery voltage can be beneficially influenced by inserting a resistor into the interrupting circuit. In the air-blast breaker limitation of the rate of recovery voltage rise is accomplished by the use of resistors inserted into the circuit by means of the action of the arc itself.

Indoor air-blast circuit breakers having 150,000-kva interrupting rating and higher are usually equipped with paralleling resistors. The method of connecting and mounting the resistor is shown in figure 11. It will be seen that the resistor is noninductively wound around the muffler housing.

As the arcing contacts *A* and *B* separate, an arc is drawn between them and the centralizing action of the air-blast forces the arc into contact with the probing electrode *C*, thereby automatically inserting the resistor in parallel with a portion of the arc during the first half cycle of arc.

As the fault current decreases after reaching its maximum value during the first half cycle, the resistance of the arc increases rapidly, so that the current tends to follow the alternative path from (4) through the resistor in series with the section of the arc from the electrode *C* to the stationary arcing contact *B*. The section of the arc between the moving contact and the electrode then becomes unstable and goes out.

The section of the arc between the electrode *C* and the stationary contact *B* is momentarily maintained after the main arc from the moving contact *A* to the electrode *C* is extinguished, but the fault current is greatly limited due to the high value of the resistance connected in series with the arc.

When the low-current arc between the electrode and the stationary contact is extinguished at or near current zero, improvement in power factor has taken place due to the insertion of the resistance, resulting in a marked reduction in the instantaneous value of the generator electromotive force at the moment of interruption.

The reduction in the rate of rise of recovery voltage obtained by the use of automatically inserted resistors is illustrated in figure 12, which shows cathode-ray oscillographic records of the voltage appearing across the contacts of an air-blast breaker during and after interruption. The upper oscillogram shows the voltage condition when no resistor was used and the lower oscillogram shows the improvement obtained by the use of resistors.

It is apparent that the rate of rise and the maximum value of recovery voltage is much less when an automatically inserted resistor is used. High-frequency transients are practically eliminated and the voltage immediately following arc interruption, follows generally the normal sinusoidal wave form. A representative oscillogram of an interrupting test made on an air-blast breaker equipped with resistors is shown in figure 13.

Summary

It is evident from the foregoing description that the air-blast breaker has several very desirable characteristics.

1. It is an oilless breaker.
2. It can be applied over practically the same range of interrupting-capacity steps and voltages as the oil circuit breaker, both indoor and outdoor.
3. The prestored energy of compressed air is used, not only for circuit interruption but also for opening and closing contacts, and for proper sequential timing.

4. Its current-interrupting range is such as to meet the maximum interrupting-current requirements on each interrupting step.

5. It gives control over the magnitude and rate of recovery voltage rise.

6. Short arcing time permits fast interrupting time.

7. Separation of interrupting and isolating contacts enables fast reclosing.

Conclusion

The air-blast breaker is a scientific product which is a direct result of the availability of high-power circuit-breaker testing laboratories. Its performance under all kinds of conditions, has been checked and rechecked; its operating characteristics and limitations have been determined; and operating security has been assured by the application of adequate safety factors and interlocks.

As a result of the extensive research conducted during the evolutionary process, it is possible to predetermine the performance of this air blast circuit breaker by means of a judicious combination of air pressure, port area, series breaks, and arc paralleling resistors. And so there emerges from the testing laboratory, a unique oilless circuit breaker of simple, sturdy and compact design, which is applicable to practically all current, voltage, and interrupting ratings. Comprehensive and reliable test data enable its adaption to almost any particular set of system characteristics within its rating, and prove its ability to render satisfactory service under the most arduous demands of American power systems.

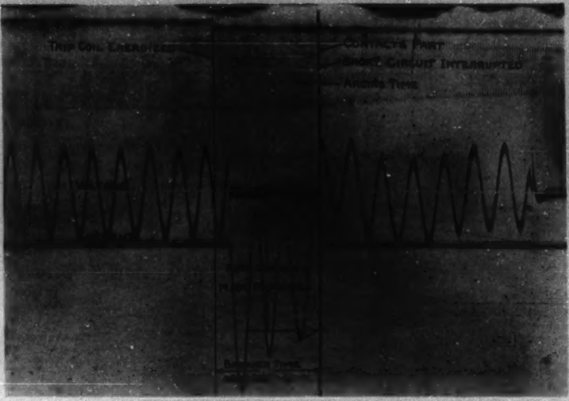


Figure 13. Oscillographic record of interrupting test of a 1,200-ampere 15-kv 500,000-kva interrupting capacity air-blast circuit breaker, when interrupting 429,000 kva at 11 kv. Arcing time 1/600 (0.00167) second

Acknowledgment

During the successful development of the air-blast circuit breaker, reliance has been placed on the co-operative efforts of many individuals. Acknowledgment is here made of valuable contributions from the staffs of the circuit-breaker testing laboratories and engineering departments of the Allis-Chalmers Manufacturing Company and of the Brown Boveri Company.

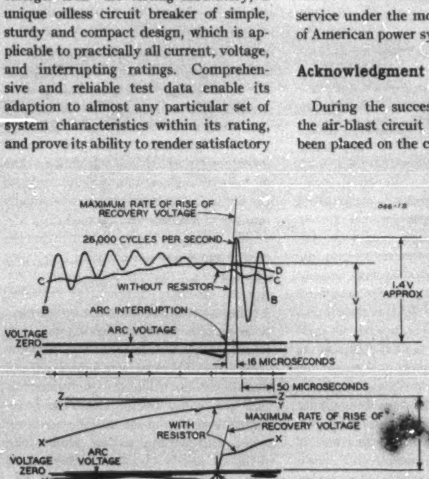

Figure 12. Cathode-ray oscillogram showing prevention, by resistor, of high-frequency transients

Upper section, without resistor, shows transient with frequency of 26,000 cycles. Record starts at *A*, continues to *B*, reappears at *B* (left), continues to *C*, reappears at *C* (left), terminates at *D*. Arc voltage decreased to zero from peak value at interruption point. High-frequency transient appeared; voltage reaching 1.4 times normal maximum sinusoidal value in the short time of 15 microseconds. Oscillations gradually decrease to *D*

Lower section, with resistor, record starts at *W*. Resistor limited voltage peak before arc interruption. Rate of recovery voltage rise greatly reduced after interruption. Voltage-wave rise rate tapered off, following approximately sinusoidal form through *X* and *Y* to *Z*. Maximum voltage value not reached until 750 microseconds

Synopsis: The designs of European air-blast circuit breakers are not wholly satisfactory for operation in the United States as they do not handle high enough currents, cannot economically be built for high enough interrupting capacities, and do not conform to United States installation arrangements.

Accordingly, a new type of air cross-blast circuit breaker has been developed which does conform to the above requirements. The commercial design of this circuit breaker is discussed in a companion paper "Design and Construction of High-Capacity Air-Blast Circuit Breakers" by Messrs. H. E. Strang and A. C. Boisseau, and the present paper analyzes the theory of performance of the foreign and cross-blast circuit breakers, and presents evidence from a number of sources which throw light on the method of operation. The circuit breaker is found to operate predominately on the displacement theory. The nature of its performance makes it much less sensitive to recovery rate and high currents and much more economical in air consumption than air-blast breakers previously available.

FOR a number of years air-blast circuit breakers have been built in Europe. These designs have been watched closely; individual breakers have been imported and tested. An air-blast circuit breaker of purely domestic design is now being put upon the market. This circuit breaker is described in a companion paper by Messrs. H. E. Strang and A. C. Boisseau (*Transactions pages 522–7*).

Inasmuch as this design differs completely from foreign practice, it is interesting to examine the reasons for this pronounced difference, and the inner workings of the new device. Figure 1 shows diagrammatically the typical Continental design, which may, for the sake of identification, be described as radial blast. It consists of a male contact and a segmental female contact through which air is discharged when the circuit breaker is opened. The air stream envelopes the male contact on its way to the nozzle. It thus tends to cool the arc and blow the arc products away from the male contact and out through the nozzle. Due to the fact that the arc is extinguished by an independent source of power, the air blast, the performance of such a circuit breaker is highly reproducible and it is an excellent design for analytical study.

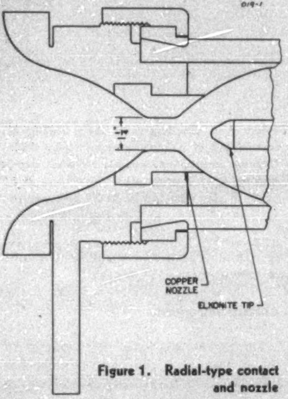

Figure 1. Radial-type contact and nozzle

A considerable number of tests has been made on nozzles corresponding approximately to the Continental designs. Figures 2*a*, *b*, and *c* give the results of such tests. In figure 2*a*, it is shown that with voltage recovery rate and air pressure constant, the current-interrupting capacity is proportional to nozzle diameter. In figure 2*b* it is shown that with voltage recovery rate and nozzle diameter constant, the current interrupted is proportional to air pressure. In figure 2*c*, it is shown that with pressure and nozzle diameter constant, current-interrupting capacity is inversely proportional to recovery voltage rate between limits. This inverse proportionality fails at high currents, therefore, there is a maximum current which can be cleared no matter how low the rate of rise of recovery voltage may be. The design of figure 2*c* corresponds to a Continental rating of 400,000 kva at 10 kv or 23,000 amperes. Examination of the figure shows that at this rating the recovery rate must be quite low, 150 volts per microsecond at 120 pounds per square inch and about 500 volts per microsecond at the breaker's rated pressure, as compared with a figure of 1,800 for the usual testing station. It further appears that the kilovolt-ampere rating must be sharply reduced if the operating voltage is below 8,000 volts no matter how low the recovery voltage may be.

Since United States circuit-breaker standards call for interrupting current ratings as high as 60,000 amperes for a 250,000-kva circuit breaker, it is apparent that the Continental design would have to have a much smaller rating if it were to be applied in any standard manner in this country. Since the nozzle diameter increases as the first power of the current to be interrupted, while the air requirement goes up as the square of the nozzle diameter, the larger nozzle required to meet United States conditions would have a very greatly increased air consumption and would not be an economical design. A satisfactory design for the United States should be able to handle considerably higher recovery rates and at the same time should be able to handle maximum currents with a minimum of air consumption.

Accordingly the cross-blast design described in the Strang-Boisseau paper has been evolved. Figure 3 is a cross section of the interrupting unit. This consists of a pair of contacts located in an arc chute of insulating material. Air is introduced at one side of this chute. The air velocity is, therefore, at right angles to the arc stream and blows the arc against a number of barriers also of insulating material. In effect the arc is caught in the grip of a multiple shear having a movable member consisting of jets of air and stationary members of insulating material. At current zero the arc is cut up into sections and the arc products blown away (through the arc chute) into a muffling structure. This structure lends itself well to observation. All of the usual magnetic and cathode-ray measurements can be recorded and the chute can be made of transparent material so that the behavior of the arc can be observed by high speed photography. The usual high speed cameras operating up to 2,000–3,000 frames per second do not provide enough observations close to current zero. However, a special camera was developed which is capable of a maximum speed of 120,000 frames per second.[13] Since the arc phenomena in the cross-blast chute last for periods between a half and one cycle, the camera was slowed down so as to take 60,000 frames per second, that is, its total of

1,000 frames is distributed over one cycle. With this device, exposures occur at the rate of one every $16^2/_3$ microseconds, or one every 0 degree 20 minutes of arc.

Figure 4 shows some typical enlargements of arcs taken with this camera.

Although much valuable work has been done in which the voltage recovery characteristics of circuits have been assessed on the basis of the recovery rate, or the steepest tangent passing through the origin, it has nevertheless been appreciated from the earliest days of the conception that precise work along this line involved a comparison of the entire voltage recovery curve of the circuit with the curve representing recovery of insulation strength of the interrupting device. For certain other interrupting devices, notably expulsion protector tubes, curves of insulation strength recovery have been determined and published. In the present instance, therefore, an attempt was made to secure as complete a curve as possible between the recovery strength of the circuit breaker and time. In order to secure this curve the circuit breaker was subjected to varying recovery voltage rates high enough to cause the arc to restrike. A cathode-ray oscillogram of such a test shows the voltage first rising across the contacts and then collapsing at the point where a restrike occurs. The value of voltage at which collapse occurs and the associated time provides a point in the time curve of recovery of insulation strength. See appendix *C*.

The solid line of figure 5 is a plot of a recovery characteristic with a number of experimental points shown. Over a considerable range it appears that a straight line through the origin fits the observed points as closely as any other line. It therefore, appears that the conception of recovery rate, that is, a proportionate increase in strength against time, is a useful parameter for this type of circuit breaker. As the recovery voltage rises corresponding to an increasing dielectric strength in the path previously occupied by the arc, however, the point is reached where a breakdown can take place between the contacts over a new path. There is, therefore, a saturation condition. The curve bends over at some value representing the breakdown of the gap. This saturation characteristic appears as a matter of experiment in the solid-line curve of figure 5.

In figure 5, most of the experimental points correspond to a pressure of 3 pounds gauge or 18 pounds absolute. The dashed curve is calculated from the experimental solid curve for 20 pounds gauge or 35 pounds absolute. Two test points are given corresponding to this pressure. The highest points of these two curves are at 40 and 91 kv respectively, or a ratio of approximately 2.3. From the curve in figure 6, the rod-gap dielectric strengths corresponding to the two pressures and adjusted to the proper temperatures are 61 kv and 103 kv, whose ratio is 1.7. From the random nature of breakdown phenomena this is probably as close an agreement as one can expect from so few tests.

Below ten microseconds no experimental points on the solid curve appear. Some discussion will be offered as to the probable shape of the portion of the curve below ten microseconds. However, consideration will first be given to the straight portion of the curve between t_3 and t_4. This part of the curve appears to be consistent with the displacement theory of operation, that is, it is assumed that at current zero an unimpaired wedge of dielectric is driven across the arc path. This wedge increases in thickness at the rate of fluid flow and the product of that rate and the dielectric strength of the wedge gives a measure of recovery strength across the gap:

$$v/t = d/t \times v/d$$

where

v = voltage
d = distance
t = time
v/t = rate of rise of recovery voltage
v/d = dielectric strength
d/t = dielectric velocity

This equation has been evolved for the case of liquid dielectric such as oil, which is relatively incompressible and constant as to dielectric strength. With air which

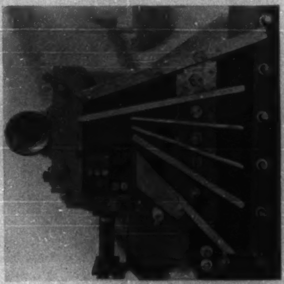

Figure 3. Cross section of interrupting unit of cross-blast air circuit breaker

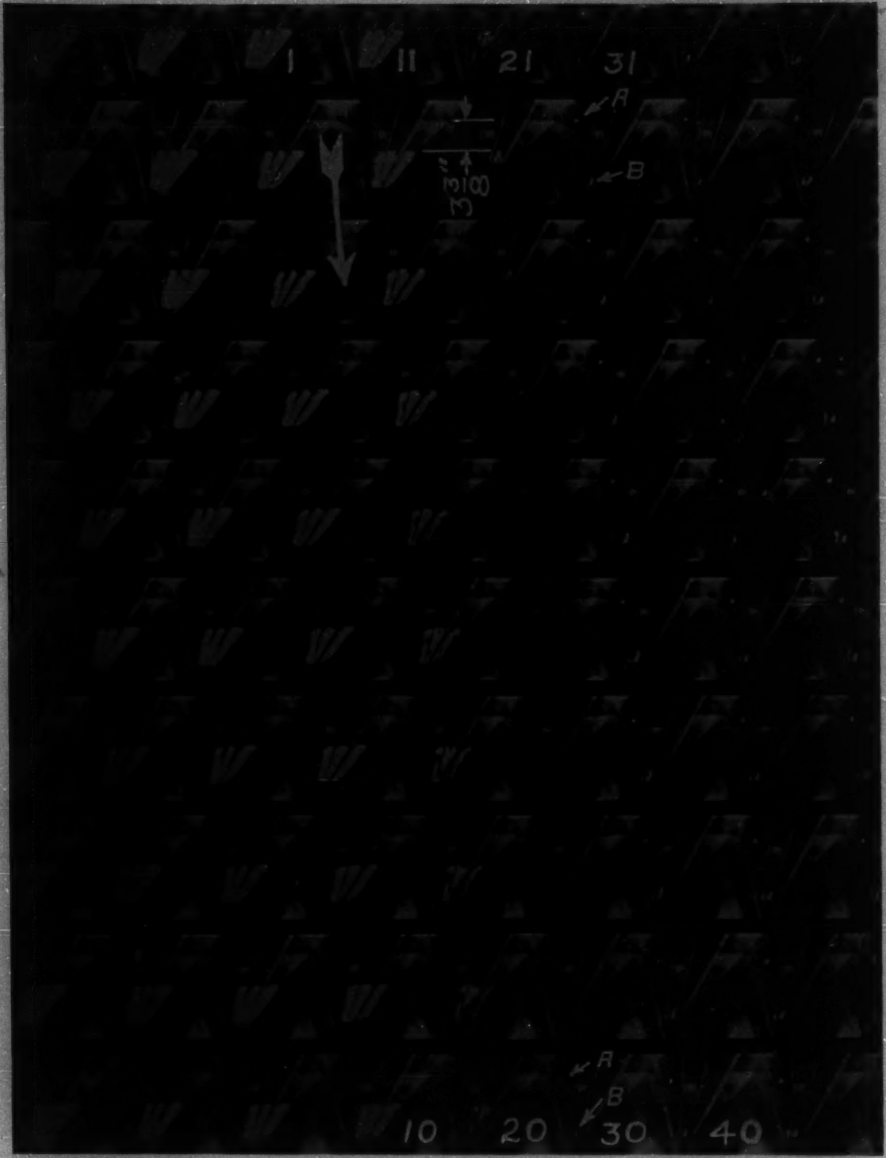

Figure 4. Photographs of the arc in a cross-blast circuit breaker taken with high-speed camera at 60,000 frames per second

Frames 1 to 25 inclusive are photographs of the arc which is decreasing as it approaches current zero in frame 23. Frame 30 shows the first breakdown, at *B*, from the moving contact to a timing gap at *A*. The breakdown of this timing gap is recorded on the cathode-ray oscillogram and makes it possible to locate the current-zero photograph. In frame 32 these auxiliary arcs appear with greater intensity. Frame 22 shows the $3^{3}/_{8}$-inch depth of the cooling plates obeys the gas laws and has a dielectric strength which is variable with pressure, the matter of determining the proper dielectric strength and velocity to use is somewhat more complicated than with oil. The curve of figure 6 has already been offered showing the variation of dielectric strength with pressure. The amount of air discharge through an orifice is expressed by the equation:

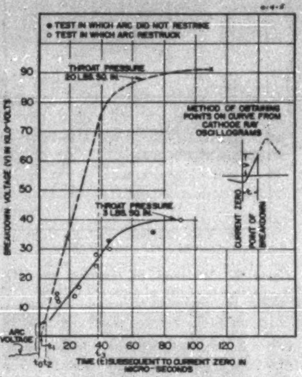

Figure 5. Variation of recovery strength of cross-blast breaker with time

$$M = Ap\sqrt{\frac{\gamma g}{RT}}$$

where

M = mass discharge in unit time
A = effective orifice area
P = absolute pressure in orifice
T = absolute temperature in orifice
R = universal gas constant
$\gamma = \frac{cp}{cv}$
g = acceleration of gravity

This equation holds provided the receiver pressure is less than 0.53 times pressure in the tank supplying the orifice. Under these conditions, the discharge will be at the velocity of sound. This condition is met by the 20-pound curve of figure 5. In the air at high velocity, the temperature will have fallen in accordance with the equation

$$T_2 = T_1\left(\frac{P_2}{P_1}\right)^{\frac{\gamma-1}{\gamma}}$$

to −71 degrees centigrade, P_1 being 135 pounds absolute.

At this pressure and temperature the impulse dielectric strength will be 103,000 volts per inch, assuming that the gap between the ionized columns is approximately equivalent to a rod gap. At a temperature of −71 degrees the velocity of sound is 938 feet per second. The data is taken under such conditions that the contacts are separated far enough to bring in to play one barrier in the arc chute. A wedge of air will be driven in on each side of this barrier so that the rate of rise of dielectric strength should be determined by multiplying the dielectric strength just obtained by the velocity of sound and by 2. The resultant figure of 2,320 volts per microsecond is well within the limits of experimental error as compared with the slope of 2,000 volts per microsecond on the dotted curve.

In the deionization or cooling theory of arc interruption the arc space is cooled and deionized. (Doctor Suits[11] has shown that these two phenomena are substantially the same at high pressure.) This cooling causes an increase in arc voltage. Prior to current zero the arc voltage is measured and it is a reasonable assumption that immediately subsequent to current zero it would require that amount of voltage or a greater amount to sustain an arc. Practically, the required voltage should be greater for two reasons. In the first place, some cooling will have taken place during the voltage reversal no matter how quickly that has occurred. In the second place, the reversal must be accompanied by the formation of a new cathode. This cathode effect, however, is small in a high-voltage design such as that under discussion. The curve of figure 5 would, therefore, be expected to start at zero time t_0 at a height corresponding approximately to the arc drop prior to current zero. During the time that the cooling is taking place this curve will rise until when the cooling has become complete the dielectric strength will increase at the rate of interposition of new dielectric. The transition from the curve to the straight line, the slope of which represents the rate of interposition of the new dielectric, is designated as t_2. It is interesting to see what evidence can be obtained regarding the time t_0 and t_2 and what effect it has upon the performance of the circuit breaker.

In this way the recovery characteristic of this circuit breaker can be divided into two parts. One part between t_0 and t_3 in which a cooling phenomenon takes place and the other period subsequent to t_2 in which the operation is on a displacement basis. During the cooling period, displacement cannot be operative because during that period some conductivity exists, and the current flowing through that conductivity disrupts the fresh dielectric as fast as it enters the arc space. As soon as unimpaired dielectric has been interposed, that fresh dielectric will sustain the entire recovery voltage. That part of the arc path still conducting will in effect be short-circuited by that conductivity. The two phenomena, therefore, would not take place simultaneously, but are present, one prior to time t_2 and the other subsequent to it. During the time t_0 to t_1 there must be some conductivity. If that conductivity is appreciable, it should represent a resistance shunted across the contacts, and should alter the curve of the voltage transient. The voltage transient of the test station is known both through calculation and tests of oil circuit breakers. See appendix *A*

An examination of the tests on the cross-blast air circuit breaker indicates conductivity only at currents above 6,000 amperes and at rates of rise of recovery voltage above 2,500 volts per microsecond. The largest observed conductivity was quite small, resulting in a reduction of the recovery transient peak of only 15 per cent. Qualitatively, if cooling is playing a part in the operation of the circuit breaker, one would expect to find some relationship between clearing and the arc voltage immediately prior to the last current zero, that is, it should be apparent that the circuit breaker is getting ready to clear by a rise in arc voltage prior to the current zero, at which point the clearing actually takes place.

Table I shows a number of tests made at varying currents and pressures together with the arc voltages immediately prior to the last current zero. There seems to be a purely random relation between the

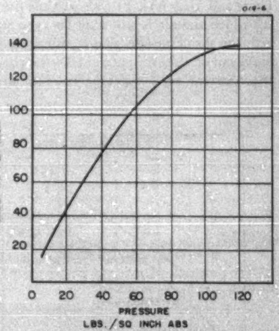

Figure 6. Variation of dielectric strength of air with pressure; Impulse breakdown of two-centimeter rod gap in nitrogen at 25 degrees centigrade

arc drop just prior to clearing, so that any effect of cooling on the actual clearing appears to be a secondary phenomenon.

Further qualitative evidence on this subject was obtained by substituting other gases for air. It is known that a small amount of carbon tetrachloride vapor will greatly increase the breakdown strength of air. Accordingly, carbon tetrachloride vapor was added and it was found that the performance corresponded to that which would exist at double the dielectric strength of pure air in accordance with the displacement theory. Since it was conceivable that this increase was due in part to the increased cooling effect from added carbon tetrachloride, a proper proportion of CO_2 was added to give approximately the same increase in the cooling effect but no measurable increase in the performance was detected.

Messrs. I. Kesselring and F. Koppelman[7,8] have proposed an interesting theory on the basis of which the time required to cut the arc path can be calculated for a radial-blast breaker. They assume that the current density in the arc stream is a constant. Under these conditions and with the round arc stream used by them the diameter of the arc is proportional to the square root of the current, a relationship which they claim to have been confirmed by photographs. In the process of cutting off the arc path, the interrupting air proceeds with some velocity. As long as this velocity is greater than the rate at which the arc diameter decreases, the unimpaired air will follow closely the receding boundary of the arc. However, with the diameter changing in accordance with the square root of current, the rate of decrease of the arc diameter approaches infinity as current zero is approached. There will, therefore, be a short time during which the air is not able to keep up with the shrinking arc, and it will not actually cut off the arc space until some time after current zero. If enough data are available this interval during which the arc path is not definitely cut off by displacement is calculable.

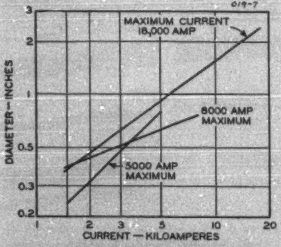

Figure 7. Variation of arc diameter with current, cross-blast circuit breaker

Doctor C. G. Suits has calculated on theoretical grounds that the current density with forced convection is not absolutely constant but that it should vary in such a way that the arc diameter will vary as the 0.77 power of the current, instead of the 0.5 power as assumed by Messrs. Kesselring and Koppelman.

The high-speed photographs provide an experimental measure of the actual diameter of the arc at least as far as it is shown by its effect on the photographic negative.

Figure 7 has been taken from measurements of arcs at three different currents, peaking at 5,000, 8,000, and 18,000 amperes. From these curves the following three formulas can be deduced:

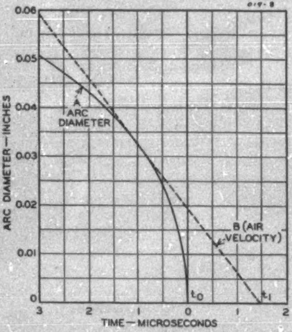

Figure 8. Variation of arc diameter with time, 8,000-ampere arc, cross-blast circuit breaker

With a maximum of 5,000 amperes

$d = 0.000288i^{1.04}$ inches

With a maximum of 8,000 amperes

$d = 0.021i^{0.4}$ inches

With a maximum of 18,000 amperes

$d = 0.00163i^{0.746}$ inches

All of these curves represent measurements during the decay of the arc.

Figure 8 is such a curve of arc diameter against time, drawn to scale with a corresponding curve of air velocity shown tangent to it. If we assume that the separation of the current zero and the arrival of the air indicates the time t_0t_1, then those times for the three currents observed are 0, 1.6, 0.0107 microseconds. From the pronounced variation in exponent derived from figure 7, one is left in doubt whether there is a change in constants with increase in current or whether the three sets of values are due to observational errors. More data should throw light on this point. All three values yield cutoff times so short that it is apparent that one would not expect cooling phenomena to be in evidence except under conditions of a high rate of rise. For instance the least arc voltage from table I is 2,900 volts and the longest time above is two microseconds, giving a rate of rise of 1,450 volts per microsecond.

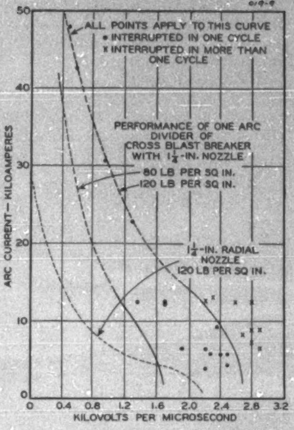

Figure 9. Variation of rupturing capacity with rate of rise of recovery voltage

This gives rise to the question of what needs to be done in the case of an application where the rate of rise of recovery voltage is extremely rapid. There are two alternatives. Either the ability of the breaker may be increased by an increase in air pressure, air volume, or the number of arc barriers introduced into the chute; or arrangements may be made to shunt the contacts with some impedance which will reduce the rate of rise. Both of these expedients can be taken. In order to secure the effect of a resistance shunt, an electrode can be located between some pair of barriers and connected through a resistance to the stationary contact. With such an arrangement the recovery voltage appearing between the contacts after the arc has been interrupted breaks down the gap to this electrode inserting the resistance in shunt with the arc path while any current flowing through the resistance is interrupted by further movement of the contact admitting air to other sections of the arc chute. In the appendix *B* will be found a simple method of calculating what

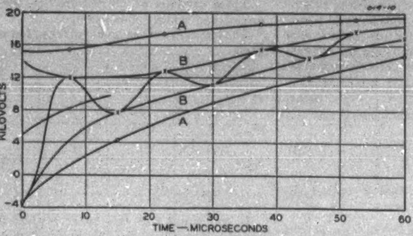

Figure 10. Envelopes of recovery-voltage oscillation, cross-blast circuit breaker

Curve *B* at reduced air pressure

the proportions of such resistors should be. From this point on, it is merely a matter of economics and design whether the recovery rate of any given circuit should be taken care of by a change in the air delivery or by the application of a shunt resistor.

The ability of the cross-blast design to handle recovery rate is much greater than that of a radial blast, particularly at heavy current.

Figure 9 is a curve of current variation with recovery rate corresponding to figure 2*c*. The curve of figure 2*c* has been superimposed and dotted for reference. In the case of the radial blast, all of the air heated by the arc and the arc products must be expelled through the same opening as the air blast. Consequently any current will reduce to some extent the air delivered. In a cross-blast design air is throttled by an orifice before entering the arc chute. As long as the back pressure is less than the critical value 0.53, the amount of air delivered will not change with current over a considerable range. The interrupting ability of the circuit breaker should, therefore, not change as much over a corresponding range and this is shown clearly in figure 9.

Some falling off in the recovery rate ability is noted, but this fall is not nearly as rapid as with the radial nozzle. At high currents gas evolved by decomposition of the chute structure begins to be added to the air discharge in such volume that it adds appreciably to the interrupting capacity of the chute. The dotted portion of the curve in figure 9 represents an extrapolation of the actual test curve beyond the point at which it was possible to secure failure to locate the curve exactly. At high currents enough gas is evolved from the chute structure to interrupt the circuit without any air supply. The extrapolation of this curve, therefore, represents ability known to be present in the interrupting structure but not necessarily the maximum capacity of it. The full-line curves of figure 9 correspond to clearing in one cycle with only one barrier in action. As the contact continues its travel two or more barriers come into action with resultant increase in interrupting ability as shown by the crosses on the figure. These points are not comparable directly with the points for one barrier since no limit in interrupting capacity was reached. It will be noted that at say 1,000 volts per microsecond the cross-blast chute interrupts over four times as much current with the same air consumption or conversely, a radial nozzle to have the same interrupting capacity would be 4.3 times as big in diameter and consume 18 times as much air.

As mentioned at the beginning of this paper, it is hoped that the foregoing will give a clear idea of the reasons why, for low-voltage designs particularly, it has been necessary to develop a new type of interrupting air-blast structure. The behavior of that structure has been analyzed and it has been shown under most conditions to operate on a displacement basis. The small area in which operation is by cooling has also been defined. For heavy currents, the ability of this design, instead of decreasing toward zero volts, actually rises until at the highest currents the circuit is interrupted even without the aid of the air blast.

Appendix A. Air-Circuit-Breaker Leakage Current*

It has been pointed out that the interruption process can be divided into two periods: one during which a path of finite resistance exists between the electrodes; and a second characterized by infinite resistance but finite dielectric strength. This fact is well illustrated by a series of tests from which the actual magnitude of the leakage resistance and current are determined. It was found that at constant recovery rate, current, and voltage, air pressure could be reduced until a leakage current flowed after the current zero.

Figure 10 shows the envelopes of the recovery-voltage oscillation as taken from cathode-ray-oscillograph records of two tests taken at the same voltage and with the same circuit. Test *B* was made at considerably reduced air pressure.

The complete circuit employed in the tests consisted of a generator and an external reactance in series with the breaker. Both generator and reactance had considerable distributed capacitance to ground, consequently the recovery voltage was composed of two frequencies, one relatively low, and the second, due to the presence of the series reactance, of the order of 60,000 to 100,000 cycles per second.

---

* Prepared by Robert M. Bennett.

For the purpose of analysis of the high-frequency oscillation, this circuit can be generalized as indicated in figure 11, in which L represents the inductance and C the equivalent capacitance to ground of the external reactance. R_1 represents the ordinary damping resistance of the circuit and might have been placed in series with the inductance without altering the final conclusions. R_B represents the breaker resistance. The vibration modulus of the high-frequency oscillation is:

$$p=-\frac{1}{2\frac{R_1R_B}{R_1+R_B}C}\pm\sqrt{\frac{1}{\left(2\frac{R_1R_B}{R_1+R_B}C\right)^2}-\frac{1}{LC}} \qquad (1)$$

Since $2\frac{R_1R_B}{R_1+R_B}C \gg LC$ the angular frequency of the oscillation is

$$\omega=\sqrt{\frac{1}{LC}}$$

and C may be determined, the inductance being known. The envelope of the high-frequency oscillation will be of the form

$$y=\epsilon^{-\frac{R_1+R_B}{2R_1R_BC}t}$$

and this envelope plotted on semilog paper has the slope

$$D=-\frac{R_1+R_B}{2R_1R_BC} \qquad (2)$$

Figure 12 shows the magnitude of the envelope of the recovery voltage during two tests, test B being at reduced air pressure.

These curves are direct evidence of the occurrence of displacement during the operation of the breaker. Curve A made at high air pressure shows that at all times after the current zero, the damping of the circuit was due to a constant value of resistance, hence the breaker resistance must have been infinite.

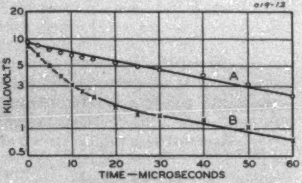

Figure 12. Magnitude of recovery voltage envelopes

Curve *B* at reduced air pressure

Curve B which indicates a greater rate of damping for 15 microseconds becomes parallel to curve A showing that in this case also displacement occurred although the air pressure and velocity were greatly reduced. The slope of curve A is given by $D=-\frac{1}{2R_1C}$ and the value of R_1 is found from the relation

$$R_1=-\frac{1}{2DC} \qquad (3)$$

If R_1 is known it is possible to find R_B from equation 2 above, that is

$$R_B=-\frac{R_1}{1+2R_1DC} \qquad (4)$$

The above method of calculation is useful for determining the breaker resistance after the first peak of the recovery voltage. For values previous to this peak the exact value of the voltage envelope is in doubt and the breaker current can be determined as follows:

Referring to figure 11

$$e_L=-L\frac{di_L}{dt}$$

and the slope of the inductance current is given by[8]

$$\frac{di_L}{dt}=\frac{-e_L}{L}$$

The capacitor current is found from the relation $i_C=-C\frac{de}{dt}$ consequently both i_C and i_L can be drawn if any single value of inductance current can be determined. Since it is evident that i_0 must be zero when $e_B=0$, it is possible to determine the inductance current at this instant by $i_L=i_0-i_C=-i_C$.

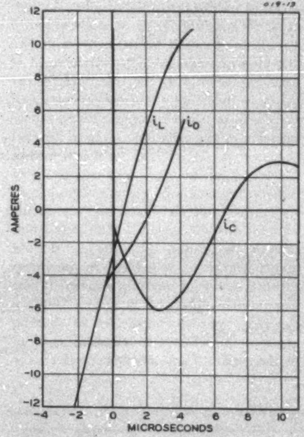

Figure 13. Construction of currents, test B

These currents as plotted for the low-pressure air test are shown in figure 13.

The resistance of the breaker is then found from

$$\frac{R_1R_B}{R_1+R_B}=\frac{e_B}{i_0}$$

or

$$R_B=\frac{1}{\frac{i_0}{e}-\frac{1}{R}} \qquad (5)$$

It was found that this latter method is useful only until the time of the first recovery voltage peak as the mechanics of constructing the inductance current introduce considerable error.

In figure 14 are shown the complete current, voltage, and resistance characteristics for the air breaker operating with low air pressure.

Points marked with circles are calculated from equation 5 and points marked with crosses from equation 4.

Appendix B†

Calculation of a Resistor for Controlling Voltage Recovery Rates

The ohmic value of resistance to limit the recovery rate to a given value is given by the equation:

$$R=\frac{\frac{de}{dt}\times10^6}{\frac{di}{dt}}=\frac{\frac{de}{dt}\times10^6}{2\sqrt{2}\pi fI}=$$

$$\frac{\frac{de}{dt}\times10^3\times V\times\sqrt{3}}{2\sqrt{2}\pi f\times kva}=3.25\frac{de}{dt}\times\frac{V}{kva}\text{ (for 60 cycles)}$$

where

R = the ohmic value of the resistance
$\frac{de}{dt}$ = the specified limit of recovery rate in volts per microsecond
$\frac{di}{dt}$ = the limit of the rate of change the instantaneous value of short-circuit current just prior to interruption
f = system frequency
I = maximum available interrupting current in rms symmetrical amperes
V = application voltage in line-to-line volts
kva = interrupting duty in kilovolt-amperes, three phase

This value of resistance should be used on each pole.

The amount of active material required may be based on the allowable temperature rise for one operation on the assumption that all of the heat developed remains in the active material. If the breaker is properly designed, the maximum duty will be about one-quarter cycle at $1^1/_2$ times leg voltage. The amount of active material is then given by:

$$M=\frac{Q}{h\Delta T}=\frac{950\times.75\times(\text{kv})^2}{240h\,\Delta T\times R}=2.97\frac{(\text{kv})^2}{h\cdot\Delta T\cdot R}$$

where

M = active material required in pounds for each pole
Q = heat generated in resistance in Btu
h = specific heat of material; Btu per pound per degree Fahrenheit
ΔT = allowable temperature rise for one operation, Fahrenheit
R = resistance in ohms
kv = application voltage in line-to-line volts

Appendix C

The type of breakdown that occurs in the air-blast breaker is of particular interest because it indicates the nature of interruption to be similar to the breakdown of a dielectric. A cathode-ray-oscillograph record of such a breakdown is shown in figure 15.

The recovery voltage rises at a rate which is in accordance with circuit characteristics and then collapses to zero voltage in less than two microseconds.

This failure of the cross-blast air circuit breaker was intentionally caused by reducing air pressure and increasing the rate of rise of recovery voltage. The character of the failure is similar to that of the disruptive breakdown of a rod gap in air.

As there is nothing shown in the oscillograph record which would indicate progressive breakdown, we conclude that it was occasioned by the overstressing of the cold air of the blast which had been inserted between the arc path ends after current zero. In other words, there was an interruption by displacement but breakdown occurred due to the fact that the recovery voltage rose faster than the dielectric strength.

In contrast with this sharp breakdown the slowness of thermal breakdown is illustrated by the magnetic oscillograph record figure 16.

It will be noted that there were attempts to interrupt which were partially successful and finally the arc was extended to a point where successful interruption was obtained. The rate of rise of recovery voltage is less than ten times faster than the 60-cycle voltage wave which is less than 40 volts per microsecond and indicates that its rate of rise was limited by leakage current.

The collapse of voltage T_1 to T_2 required approximately 2,000 microseconds which indicates clearly that it was progressive in character and was caused by a gradual decrease in the resistance of the arc path.

These two cases have been chosen as they are typical of the extremes. Figure 15 is the disruption breakdown following displacement with no deionization phenomena visible. Figure 16 is the progressive breakdown from a reversal of the deionization process with no displacement in operation.

Cases may be found where displacement and deionization by cooling may both play a part in arc interruption; however, in the cross-blast air circuit breaker, displacement will account completely for interruption at low currents and be a predominating factor even for the high currents and recovery rates.

Magnetic "De-ion" Air Breaker for 2,500—5,000 Volts

L. R. LUDWIG
ASSOCIATE AIEE

R. H. NAU
ASSOCIATE AIEE

Synopsis: The theory of quenching an arc by deionizing the normally conducting arc stream, utilizing a gas blast produced by means of an intense transverse magnetic field, is elaborated. Application of design principles dictated by this theory has made it possible to develop a new form of air circuit breaker for 2,500–5,000-volt service. These breakers are completely described, the theory of the De-ion interrupters is discussed, and test results are submitted. The problem of adequately enclosing the breakers is considered and it is shown that excellent interruption can be obtained in an enclosure of small over-all dimensions.

INTERRUPTION of 2,500- and 5,000-volt circuits capable of producing fault currents equivalent to 150,000 kva, by breakers using air as the interrupting medium, is not readily accomplished without special arc-quenching chambers. In open air impractically long arcs are necessary to clear circuits supplied at these voltages. Comparatively simple air circuit breakers have been built utilizing magnetic blowout means for lengthening the arc in an interrupting chamber of reasonable dimensions, but even with the constricted path available for the arc in such chambers, it is necessary to lengthen the arc to approximately five feet in order to achieve interruption. The energy dissipated in such an arc is necessarily high because of the long arc length and consequent high arc voltage. Interruption in such cases is not achieved primarily by establishing a process of rapid deionization in the vicinity of current zero, but depends rather upon building up the arc voltage to such an extent that restriking after an early, forced, current zero does not take place, even though intensive deionization is not provided during the time of substantially low recovery voltage following the current zero.

It is usually necessary to mount air circuit breakers for 2,500–5,000-volt applications in compact metal-clad switchgear. Consequently, efficient interruption with a minimum of arc energy, size of interrupting chamber, and formation of ionized gases is required. These features call for the development of arc-interrupting means which will open the circuit using a comparatively short arc, relatively low energy input, and effective deionization at the first current zero. In the next sections a circuit breaker is described which has these qualities and which is shown to be adequate for 150,000 kva at 2,500 or 5,000 volts when mounted in enclosures of small dimensions.

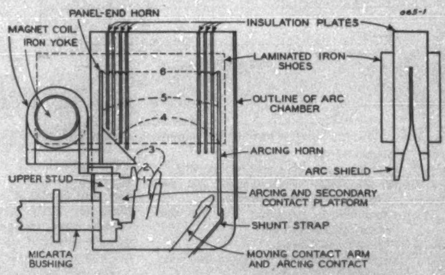

Figure 1. A diagrammatic sketch showing partial sections of the magnetic De-ion interrupter

The dotted lines 1, 2, 3, 4, 5, and 6 indicate progressive positions in arc interruption

De-ion interrupter

To interrupt an a-c circuit with minimum dissipation of energy, a switch is required which does not substantially impede the flow of current until it normally reaches zero, and which quickly takes on insulating properties thereafter. This means appears to be more advantageous than depending upon a high arc voltage and the associated high energy input to effect interruption. Synchronization of interruption with a current zero may be obtained by separating switch contacts and forming an arc which must be controlled to develop dielectric strength, following the current zero, more rapidly than voltage is impressed by the circuit.[1] This deionization action may be accomplished in a number of ways—for example, by the use of a blast of gas produced by decomposing a gas-forming material,[2] or by the use of a plurality of copper plates with short arcs between them to take advantage of the spectacular dielectric recovery at the cathode of an arc.[3] A more recent method which employs a magnetically produced gas blast for deionization was presented by Ludwig and Grissinger in their paper "A New High-Capacity Air Circuit Breaker".[4] An experimental review of the various interrupting means available indicated that this latter method was most suitable for interruption of high currents at 2,500 and 5,000 volts, because of its simplicity, effectiveness, and freedom from undesirable flame and noise.

Application of the magnetic-deionizing principle results in constructing an interrupting chamber as shown diagrammatically in figure 1. The chamber consists of a large number of non gas-forming insulating plates having V-shaped slots which are spaced apart and placed at right angles

---

Paper 40-65, recommended by the AIEE committee on protective devices, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 10, 1939; made available for preprinting December 20, 1939; released for final publication March 27, 1940.

L. R. LUDWIG is division manager, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.; R. H. NAU is with the same company.

to the arc path. During operation an arc is drawn between separating contacts, and is then magnetically moved toward the closed top of the slots in the insulating plates. At this position the presence of a strong magnetic field imparts to the electrons in the arc an upward component of velocity. They in turn bombard gas particles and produce an actual blast of gas perpendicular to the arc, which action requires the arc continuously to ionize fresh gas in considerable quantities. When current zero is reached this action continues in a sufficient degree effectively to deionize the plurality of short lengths of the arc near the edges of the plates. Dielectric strength is consequently established.

The insulating plates are made of a material which does not form gases in order to prevent unnecessary display of ionized flame in the air space above the interrupting chamber. Flame from the arc core must pass upward between the closely spaced plates for a distance of several inches before reaching free air space. During this passage contact with the cool walls of insulating material deionizes the flame so that upon reaching the free air space beyond the chamber there is no danger of external flashover of the arc chamber or to metal parts of the enclosure in which the breaker is mounted.

This principle of deionization is applicable to a wide range of voltage. The magnetic-field strength, thickness of the plates and the space between the plates, and the shape of the slot determines the volts per plate at which a given current can be interrupted. The number of plates used may be suitably chosen along with the other parameters to make the interrupter adequate for specified current and voltage ratings.

In the case of the 600-volt air breaker previously described[4] sufficient field strength to give the required volts per plate was obtained by the use of iron plates built in above the insulating plates and in the same plane with them. However, for the higher-voltage circuits iron has been added in the form of a laminated structure about the chamber, and a multiturn coil is connected to provide a very intense field. The iron structure is shown diagrammatically in figure 1.

The figure also shows an outline of one of the deionizing plates. The slot into which the arc is forced by the magnetic field is long and quite narrow at the top. When the current in the arc is high during most of the half cycle preceding interruption, the arc cannot reside in the uppermost portion of the slot because the cross-sectional area required by its core is large compared to that available in the upper slot region. The effect of this construction is to permit the arc to operate with a low voltage drop until just prior to current zero, and thus the energy dissipated in the interruption is reduced. The arc voltage, as shown on the oscillograms in figures 4 to 9, indicates the effectiveness of the slot design in limiting the arc voltage. The design of the slot differs from that of lower-voltage breakers which are also applied for d-c interruption.

C—60-cycle timing wave

Plates approximately one-eighth inch thick are found experimentally to be most suitable. The space between the plates may be varied from one-eighth to one-fourth inch, depending on the magnitude of the current to be interrupted and the voltage. An arc length of $9^1/_2$ inches between horns at the two ends of the chamber is sufficient for interruption of 150,000 kva at either 2,300 or 5,000 volts. Rms voltages as high as 550 volts per inch or 140 volts per plate have been interrupted when the short-circuit current was approximately 22,000 amperes. An interrupting device of this type remains substantially constant in kilovolt-amperes and it is found that higher currents can be opened at lower voltages or that higher voltages can be cleared satisfactorily if the current is less.

In order to make all plates effective in the longer chutes for the higher circuit voltages, arcing horns are necessary at both ends of the chamber. These consist of copper bars placed vertically at each end of the chute. The lower terminals of the panel-end horn are sloped toward the arcing contacts of the breaker to facilitate transfer of the arc to them. The horns are slotted to release gas pressure which would tend to prevent intimate contact between the arc and the horn at the moment of transfer. The multiturn coil at one end of the chute is electrically connected between the arcing contact at that end and the horn. Therefore, the coil does not pass current except after the contacts have parted and the arc terminal has transferred to the horn, thus introducing the coil into the circuit.

Air-Breaker Construction

Breakers for 150,000 kva can be constructed in such reasonable dimensions that one can be mounted above another if desired, and therefore the draw-out type of design is particularly advantageous. The fabricated steel frame, as shown in figure 2 and figure 3, serves to support the four component subassemblies of the breaker, and has wheels attached at the bottom for withdrawal from a metal cubicle. The subassemblies are the contact structure, electric mechanism, arc chutes, and barrier system.

The contact structure of an air breaker has two functions to perform, that of carrying the load current and of drawing the arc which serves as the interrupting element. It is important to segregate these functions carefully in order to save the current-carrying or main contacts from any effects of the arcing. Also, the interrupting or arcing contacts must be designed to withstand the magnetic and thermal stresses placed on them. The main contacts are self-aligning bridge members of copper and the actual contact is made between bars of silver-nickel composition brazed to copper. The lower main contact is protected from arcing by a parallel shunt. The upper main contact is shunted by both secondary and arcing contacts which open in turn after the main contacts have parted. A horizontal overlapping barrier system isolates the main contacts from gases thrown downward by the arc.

The necessary relative motion between the two upper contacts and the main contacts is obtained by limited travel of the upper contacts on the stationary-contact side of the switch. The upper contact springs are enclosed by a platform member which has limited travel, and are thereby well protected from burning. An inverted U shunt is also enclosed within this platform member and is designed so that the magnetic force set up by the short-circuit current presses the secondary contacts tightly together in addition

to the springs. Parallel-path protection is thus provided for the main contacts to prevent them from opening any portion of the interrupted current. Tungsten-alloy contacts are provided for the secondaries and arcing tips.

Insulation of the contact structure and mechanical support is obtained by Micarta bushings through which the electrical connection is carried to the rear of the breaker.

The electric operating mechanism together with trip-free levers comprises a unit which is mounted horizontally in the base of the breaker. The mechanism actuates a cross bar which is mechanically connected to each moving contact arm by an insulating operating rod. The principal advantage of the mechanical construction is high speed, which results in only a half cycle of arcing at most currents.

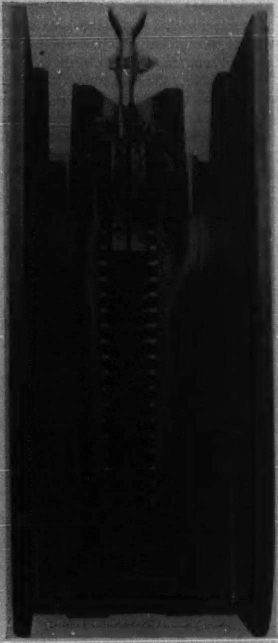

Figure 10. Arc chamber which was used during 27 interruptions at maximum short-circuit currents and also for 76 interruptions at currents of 14,000 amperes and below. The insulating plates are in satisfactory condition for further service

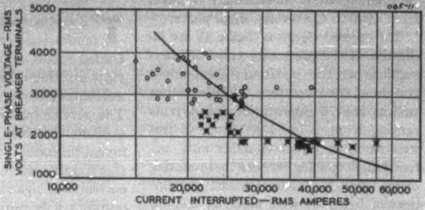
The arc chamber previously described is withdrawn from the breaker by pulling forward and using the laminated iron field structure as a support.

The function of the barrier system is to isolate electrically the live phases from each other and from the metal enclosures, particularly during the interrupting period when free ionized flame tends to expedite flashover. Obviously, the requirements of the barrier system are lessened if the interrupting chamber is made efficient so that only a small quantity of flame is allowed to escape. An enclosed space is provided by the barrier system above each arc chamber for the discharge of hot gases, which would otherwise build up pressure above the arc in the chute and hinder its interrupting ability. In this space the gases mix with cool air, and residual flame is suppressed. Muffling action is also secured by the barriered space. The barrier structure is built as a unit of insulating material and is supported from the breaker frame at the top.

Figure 11. Magnetic De-ion circuit breaker single-pole interruption tests



Crosses indicate tests made on a single arc chamber whose insulating plates were spaced one-fourth inch apart

Circles indicate tests made on a similar arc chamber whose insulating plates were spaced one-eighth inch apart

Test Results

Interrupting tests have been made on the breaker through a voltage range of 1,900 to 4,000 volts single phase, using the maximum plant capacity of the Westinghouse high-power laboratory. Figure 4 is an oscillogram showing the interruption of 39,000 amperes rms at 1,900 volts across one pole of the breaker. The equivalent three-phase kva is 150,000. The voltage element connected across the breaker terminals shows that the arc drop remains comparatively low until nearly the end of the single half cycle of arcing.

Figure 5 shows a closing-opening operation at the same voltage and with the same plant setting. The crest value of the current following closure was 89,000 amperes, and the rms current interrupted was 38,500 amperes.

Figure 6 shows the interruption of 27,500 amperes rms at 3,000 volts single phase. In figure 7, the interruption of 22,000 amperes rms at 4,000 volts single phase is illustrated. Both oscillograms show less than a half cycle of arcing.

A three-phase interruption record is illustrated in figure 8. The line-to-line potential in this case was 2,300 volts. The total kilovolt-amperes interrupted was 124,000, and the rms current opened by the center phase was 39,000 amperes rms. This test was made with the breaker completely enclosed in a metal cubicle which was at ground potential. Demonstration such as flame was entirely absent, and noise was at an acceptably low level.

Interrupting tests have been made throughout the current range with 2,300 volts across a single pole. The time of interruption increased to 20 cycles at 22 amperes, and then decreased to one-half cycle at 9 amperes. All interrupting tests were made with only reactance in the circuit, and consequently at low power factor. The typical oscillogram of figure 9 shows an interruption of 630 amperes rms at 2,300 volts single phase.

The arc chamber is not damaged by high-current short circuits. Figure 10 shows a photograph looking up into an arc chamber which had been used during 27 interruptions at the maximum short-circuit current of the laboratory, and in addition 76 interruptions of currents of 14,000 amperes and below at 2,300 volts single phase. The oscillograms of figures 4, 5, and 9 and phase three of figure 8 were made using this De-ion chamber.

In figure 11 points are plotted to semilog scale of currents interrupted at various single-phase voltages. Sixty-one test points are shown, based on currents interrupted up to 55,000 amperes rms at 1,900 volts, and voltages as high as 4,000 volts, single phase. A curve corresponding to 150,000 kva is also drawn, and the number of successful operations above the curve and throughout the voltage range indicate a good margin of safety in the breaker over this rating. This figure also indicates that the kilovolt-amperes which can be interrupted is substantially constant from 1,900 to 4,000 volts, single phase.

The crossed circles of figure 11 are indicative of the previously noted 27 interruptions at the maximum short-circuit current of the laboratory. These tests as well as the 76 interruptions of currents ranging from 9 to 14,000 amperes rms were made on an arc chamber with one-fourth-inch spacing between the insulating plates, figure 10. The 34 circled interruptions of figure 11 were made on this arc chamber using similar insulating plates spaced one-eighth inch apart.

Conclusions

The high efficacy of the new De-ion circuit breaker to function at and above 150,000 kva with 2,500 to 5,000 volts demonstrates the practicability of the interrupter utilizing a gas blast which is produced by means of an intense transverse magnetic field. This interrupter is particularly desirable because the noise and demonstration usually found in air-circuit-breaker practice is greatly reduced. The ionized gases and other by-products of arc interruption are sufficiently controlled by the interrupter that unusual barrier arrangements are not needed. The new De-ion air circuit breaker is a particularly compact and sturdy device for use in modern clad switchgear, or for separate mounting.

Design and Construction of High-Capacity Air-Blast Circuit Breakers

H. E. STRANG
MEMBER AIEE

A. C. BOISSEAU
NONMEMBER AIEE

THE air-blast principle of circuit interruption is a recent introduction to the United States, although interrupting devices utilizing compressed air have been available in Europe for a number of years. The service performance of European breakers has been satisfactory, but inherent limitations prevented adoption in this country where large values of fault current and high rates of rise of recovery voltage are the rule rather than the exception. Exhaustive tests on forms of available air breakers heretofore available have shown that approximately 40,000 amperes represents the maximum current that can be safely interrupted at generator voltage, and then only under conditions of moderate rate of rise of recovery voltage. This fact alone made it essential, if air breakers were to be utilized, to develop an entirely different type, since applications in this country have commonly required oil breakers with interrupting ratings up to 60,000 amperes at 15 kv. Even this value of current does not represent the maximum requirement, since an increasingly strong demand exists for ratings at least up to 100,000 amperes at 15 kv or 2,500,000 kva.

It was believed that the principle of arc interruption by means of compressed air was sound, particularly for the higher interrupting ratings, so a development program was undertaken to overcome the previous limitations. Breakers with interrupting ratings as high as 1,500,000 kva (60,000 amperes at 15 kv) have already been built and tested, and design tests have been made which assure the availability of breakers of higher ratings when required by the industry. Two breakers rated 500,000 kva have been in service since early in November 1939, on the Consolidated Edison system. A number of 250,000-kva breakers of this same general type have been supplied for use on systems of the American Gas and Electric Company.

Theory of Operation

The principle of interruption of the air-blast breaker is similar in many respects to the principles that have been thoroughly substantiated by both service experience and factory test with the oil-blast breaker. Fundamentally the theoretical basis of operation of the breaker is the displacement of the arc stream and the replacement of the arc products with insulation at a rate which will prevent break down of the dielectric by the recovery voltage. As applied to the air-blast breaker a stream of air under pressure displaces the arc stream and at the zero point of the current wave, purges the interrupting chamber of the hot gases. The flow of air across the separating contacts then provides the necessary dielectric strength at the required rate to prevent breakdown by the recovery voltage. A more complete exposition of this theory as applied to the air-blast breaker is contained in a companion paper by Messrs. Prince, Henley, and Rankin (*Transactions pages 510–17*).

Design Features

The actual design features of the breaker may be broken down into four major components in order to facilitate description:

1. Arc chute and movable contact
2. Air-blast valve
3. Operating mechanism
4. Control valve

The arc chute is a box structure of simple, compact design combined with great mechanical strength. Within this structure are the interrupting chamber, stationary contacts, cooling plates, arc barriers, and exhaust vent. Figure 1 illustrates the arrangement of the various parts of a typical chute designed for a 15-kv breaker with an interrupting rating of 500,000 kva. This chute is mounted in the breaker cell on porcelain insulators, and arranged to be easily removable for inspection.

Paper 40-63, recommended by the AIEE committee on protective devices, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 24, 1939; made available for preprinting December 21, 1939; released for final publication March 27, 1940.

H. E. Strang is managing engineer, large oil circuit breaker division, General Electric Company, Philadelphia, Pa.; A. C. Boisseau is with the same company.

The section at the right containing the fixed contacts, is the chamber in which the actual interruption of the arc occurs. The sides consist of blocks of insulation material with a contour designed to force the blast of air directly across the arc stream. A false top barrier containing an opening with relatively small clearances, through which the movable contact passes, forms the top while the back plate of the arc chute is also the back of the interrupting chamber and contains the entrance orifice for the air blast. The fixed-contact assembly is at the bottom of the chute, centrally located between the two insulating blocks.

Arc barriers placed at the exit of the interrupting chamber divide this portion of the interior of the chute into four passages each equipped with cooling plates. A fifth passage which also contains a cooler exists between the false and actual top barriers. All of these passages exhaust into a vertical vent where additional cooling members are installed.

The orifice in the back plate of the arc chute is located so that the normal flow of air is directly across the fixed contacts and in the plane of the longitudinal axis of the tips of the fingers. This flow of air forces the arc between the streamlined side members of the interrupting chamber and into the exit passages at the front of the chamber. In order to obtain short arc duration and minimum deterioration of parts, approximately 15 cubic feet of free air at 150 pounds initial pressure are required for a closing-opening operation on a triple-pole 15-kv 500,000-kva breaker while a 1,500,000-kva breaker requires approximately 25 cubic feet for such an operation.

The arc barriers are for the purpose of cutting the arc into sections and securing a maximum rate of increase in dielectric strength of the arc path. These barriers are of different thickness in order to equalize deterioration under the various interrupting conditions within the rating of the arc chute. The area of the passage enclosed by the barrier is proportional to the current to be interrupted while the number of passages is determined by the maximum rate of rise of recovery voltage. For 15-kv applications, tests have shown that normal interruptions up to full rating usually utilize only the first passage. The additional passages provide adequate factors of safety where high rates of rise of recovery voltage may be encountered and for that reason three barriers are used in the 15-kv arc chutes to form four exhaust passages.

The coolers are composed of stacks of thin copper plates located in the plane of the exhaust. These perform the function of cooling the exhaust gas to a point where it will not cause restrike on the outgoing side of the chute. The size and number of these stacks are determined by the current-interrupting rating.

The passage above the false top barrier allows the moving contact to be withdrawn without the external discharge of hot gases. It provides a chamber in which the time for the contact to pass through is sufficiently long to permit the air flow to completely purge the arc chute following circuit interruption, before uncovering the opening in the top barrier. The action within the section formed by the false and top barriers provides what is in effect a turbulent seal to prevent discharge around the moving contact without the necessity of a complex mechanical seal. The moving contact then finishes its stroke at which time it is completely withdrawn from the arc chute, thus providing the positive insulation of a clear air-break distance between open contacts. This also facilitates contact inspection, since the blade and its arcing tip are readily visible from the front of the cell when the breaker is open.

The exhaust gases are collected in a vent pipe of insulation material, where they are permitted to further cool and expand. Complete cooling and elimination of objectionable noise are assured by the final set of cooling plates located at the upper end of the vent pipe, where discharge takes place in the open air.

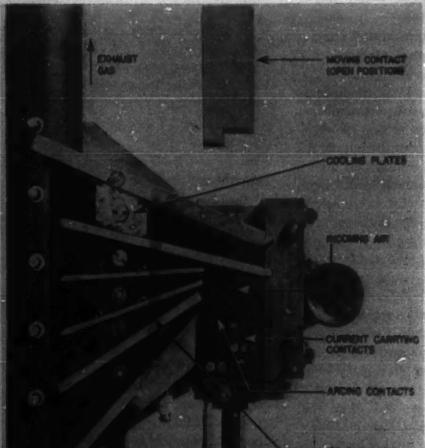

Figure 1. Cross section of arc chute of 500,000-kva breaker

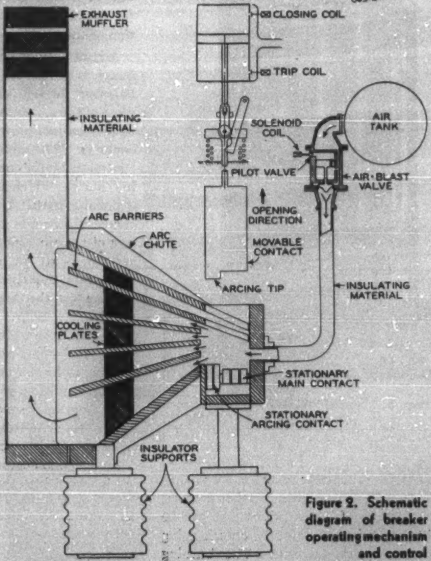

Figure 2. Schematic diagram of breaker operating mechanism and control

The stationary contacts consist of a suitable number of primary fingers to carry the normal rated current without excessive heating and secondary fingers consistent with the maximum current to be interrupted. The primary fingers are of the short-wipe line-contact silver-surfaced type that have been employed on various types of oil breakers for a number of years. These fingers are spring loaded with one end in contact with the stationary block and the other in contact with the movable blade, assuring a high-pressure silver-to-silver connection with the complete elimination of flexible shunts.

The secondary contacts consist of heavy copper fingers, surfaced on the burning area with a silver-tungsten alloy to minimize deterioration and prolong the life of the entire stationary contact assembly. These fingers are provided with a copper shunt to eliminate burning caused by vibration at the instant the movable blade engages the stationary contact, and facilitates current transfer on the opening operation. The secondary fingers are arranged to engage first and break last and, thereby, prevent burning on the primary contacts. An arcing plate has been incorporated in the design to further increase the number of interruptions that can be obtained without seriously deteriorating the stationary contacts. The burning surfaces of this plate are surfaced with a silver-tungsten alloy and are so placed that the arc is immediately transferred to it by the blast of air so the majority of the arcing occurs at this point instead of on the secondary fingers. All of these contacts and the stationary arcing plate are mounted as a unit assembly, which is easily removable from the chute for inspection or renewal.

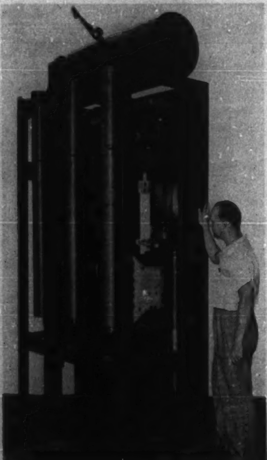

Figure 3. Typical 500,000-kva breaker complete in steel cell

The movable contact is a flat blade of copper, completely silver-surfaced, and equipped with a silver-tungsten alloy arcing tip. Silver-surfaced fingers, similar to the primary fingers, are mounted on the movable contact guide to provide a connection between the blade and entrance bushing. This method of making connections between movable and stationary current-carrying members is simple and compact, eliminating flexible leads or pigtails. Adequate tests have proved it to be satisfactory under all possible operating conditions.

In order to arrive at a satisfactory design of arc chute, numerous tests were made on various configurations and in many cases the action that takes place within the chute during interruption, was photographed.* The following description of the operation is, therefore, based on analysis of these high-speed photographs, as well as magnetic and cathode-ray oscillograms, which studied jointly, were of considerable aid in understanding the underlying theory and actual operation of the air-blast breaker.

Air, at a tank pressure of 150 pounds gauge, is introduced into the interrupting chamber through an orifice in the back plate of the arc chute and is so timed as to be present just prior to the parting of the contacts. The direction of flow of air is controlled by the contour of the interrupting chamber which also confines the arc to a definite path. Under this controlling condition, the flow of air forces the lower root of the arc from the tips of the secondary fingers to the surface of the arcing plate and is effectively prevented from restriking on the finger contacts by the positive flow of air. Arcing occurs on the secondary fingers for only a small fraction of the total arcing time and it is, therefore, possible to form a very accurate estimate of the condition of the stationary contacts from an inspection of the movable blade, which is fully exposed when the breaker is in the open position.

As the contacts move further apart the arc is forced into the first passage of the chute and lengthens rapidly. At the first current zero the stream of air removes the heated gases from between the contacts, placing a stream of clean air under pressure across the normal arc path. If the separation of contacts is sufficient for the dielectric strength of the air to withstand the recovery voltage, the arc has been successfully cleared. Inasmuch as the air in the interrupting chamber is under pressure, its dielectric strength is considerably greater than under normal atmospheric conditions and is sufficient to prevent restriking of the arc with only a short separation of the contacts.

If the contact separation at the first current zero has not been great enough to withstand the recovery voltage, the arc restrikes and interruption will occur at the next current zero. As the contact separation increases, additional barriers are brought into action forcing the arc to follow a path of rapidly increasing length. The speed of separation of the contacts is approximately three inches per cycle during this part of the stroke and by the second current zero from parting of the contacts, the separation is adequate to prevent the recovery voltage from causing the arc to restrike.

The movable contact is finally completely withdrawn from the chute, and during its passage through the last section, the gases are swept from the arc chute, and the air blast is shut off before uncovering the opening in the top barrier.

During the closing operation a blast of air is started across the contacts just prior to the time they meet. This very effectively prevents the arc from striking on the current-carrying parts and sweeps clear of the chute any gases which may be formed when the arcing contacts meet.

Blast Valve

For the arc chute to function properly, it is essential that a reliable valve be used to control the admission of the air blast. A high-speed differential-type solenoid-pilot operated valve has been designed for this purpose. The valve consists essentially of a bronze body with integrally cored air passages, a piston-operated main valve, and a solenoid-operated pilot valve. Poppet-type valves in conjunction with moderately soft seats have been utilized for their simplicity, speed of operation, and low leakage factor. It is of primary importance that the pressure drop of the valve be kept as low as possible and every effort has been made to provide a straight-line flow with a minimum of obstructions. Under intermittent flow conditions at a rate of 7,800 cubic feet of free air per minute, the pressure drop through this valve

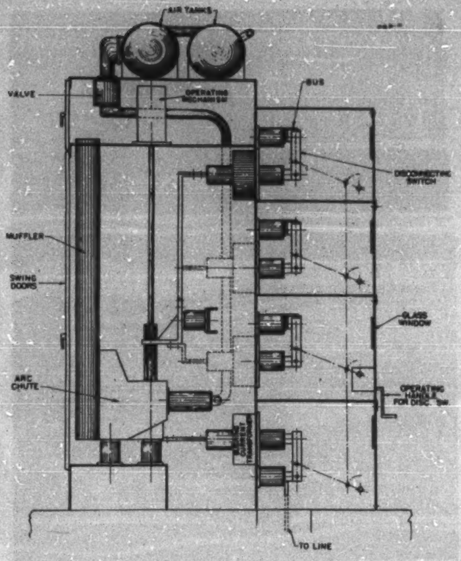

Figure 4. Application of air-blast breaker to metal-enclosed cubicle arrangement, complete with bus, disconnecting switches, and current transformers

is only about 10 pounds with an initial tank pressure of 150 pounds gauge. High speed of operation has also been obtained as the over-all operating time, from energizing the pilot valve control to complete opening of the main valve, is less than 2 cycles on a 60-cycle basis.

The blast valve is opened by energizing a solenoid, unbalancing a spring-loaded pilot valve. This allows the air to escape from above the piston at a greater rate than can be supplied by a small bleed hole from the high-pressure system. The unbalance in pressure on the two sides of the piston causes the piston to move, lifting the main valve from its seat. At the end of the piston stroke a small valve in the piston face is automatically opened, permitting a rapid flow of air to the area above the piston, but not sufficient to influence the operation as long as the pilot valve is open. This arrangement assures rapid closing of the pilot valve. With the valve in the closed position, the air under pressure holds it closed and prevents leakage.

Operating Mechanism

Mechanical operation of the contacts of this breaker is by means of a pneumatic mechanism, utilizing air pressure for both the closing and opening strokes.

Essentially the operating mechanism consists of two units, a double-ended driving cylinder and a straight-line linkage mechanism. Figure 2 shows a schematic diagram of the mechanism and control-valve equipment. The piston is directly connected to the straight-line linkage mechanism through a pair of slotted links which permit a short stroke of the piston before motion is transmitted to the contacts. To close, air pressure is applied to one end of the cylinder until the breaker is completely closed and latched in this position by a prop. On completion of the stroke, a mechanically operated switch opens to de-energize the closing control-valve solenoid.

The blast of air on closing is controlled by an interlock switch which both energizes and de-energizes the solenoid on the blast valve pilot at a predetermined point in the stroke.

The opening operation is practically the reverse of the closing operation. Air is applied to the opening side of the piston, and the first part of the motion provided by the slotted link arrangement is utilized to remove the latch. The accelerating springs rapidly bring the movable contact up to speed which is maintained by the air pressure until the blade passes the false barrier in the arc chute. At this point motion is decelerated by the action of a special dashpot, before allowing the operation to be completed. As in the case of the closing operation, air completes the opening stroke and is then cut off by a mechanically operated switch.

At the point where the blade is passing through the last section in the arc chute, an interlock switch opens to de-energize the blast of air. The mechanically operated switches used in the control of the mechanism and blast valve are directly

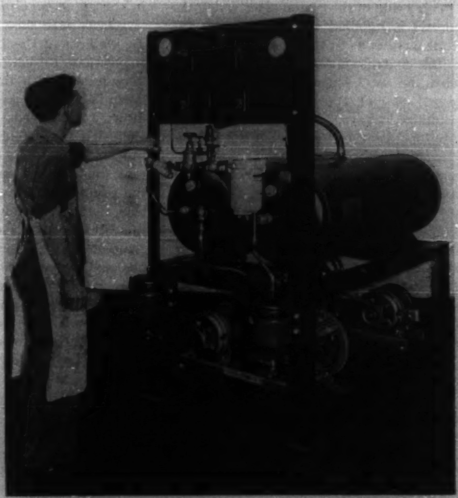

Figure 5. Typical compressor equipment for battery of 12 500,000-kva breakers

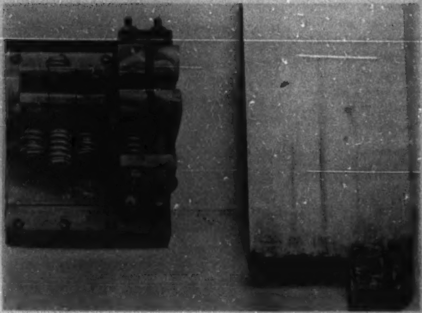

Figure 6. Condition of stationary and movable contacts following test

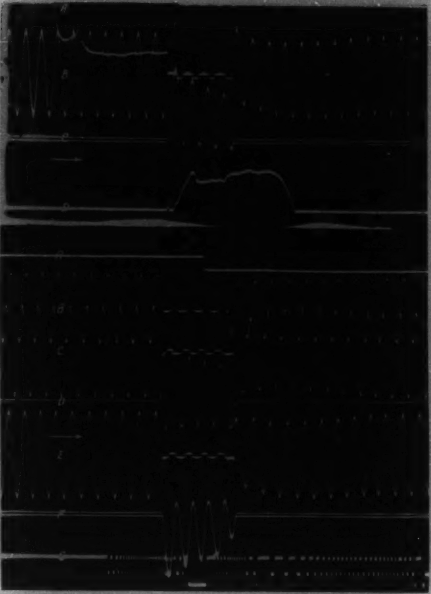

Figure 7 (right). Oscillogram of three-phase closing-opening test, interrupting 680,000 kva at 14,500 volts

connected to the mechanism. They are easily and accurately adjusted by movable cam surfaces and are of a simple and rugged construction.

Control Valves

On closing the operation is controlled by energizing the closing control-valve solenoid to admit air to the closing end of the cylinder after which the remainder of the operation is performed automatically by the sealing-in circuits and interlock switches. The opening stroke is initiated by energizing the blast-valve pilot since it is of primary importance to insure air being present at the contacts at the time of their parting. The blast-valve control is energized and motion of this valve actuates the valve which admits air to the opening side of the piston after which the control is handled automatically in the same manner as on the closing stroke.

The control valves used in conjunction with the mechanism are of the spring-biased poppet type with soft seats to minimize leakage. In order to prevent a false operation of the mechanism in case leakage does occur, the valves are so arranged that the passage to the cylinder is open to the atmosphere when the valves are in the closed position.

The closing and opening valves are interlocked in such a manner that the opening valve takes precedence over the closing valve under all conditions and provides the necessary trip-free operation of the mechanism. The operating mechanism is, therefore, fully trip free since an opening operation may be initiated at any time during the closing stroke.

General Arrangement

Figure 3 shows a typical 500,000-kva breaker mounted in a steel cell, with both terminal connections located at the bottom, and with the mechanism and air storage tank mounted at the top. A bottom-and-back arrangement can also be made in this same type of structure. Conclusive tests have shown that the interrupting element of this breaker is insensitive to position; the contacts may be mounted horizontally with the blast either up or down, or the moving contact may be drawn downward. Therefore, where local structural conditions require, an arrangement may be made with the storage tank and mechanism at the bottom, and the terminals at the top or the top and back. Figure 4 shows the application of this breaker to a metal-enclosed cubicle complete with disconnecting switches, bus, and current transformers. This construction provides a ready means of interlocking the gang-operated disconnecting switches with the cell doors, to permit entrance to the breaker cells only when the parts are safely disconnected from both bus and line.

Air Supply

In the case of these high capacity breakers, each breaker will have its own individual air storage tank, containing a sufficient supply for two closing-opening operations at full interrupting rating. A central compressor and storage system may be located at any convenient remote point, and connected by a manifold and nonreturn valves to the breaker unit tanks. These nonreturn valves assure the retention of sufficient air at each breaker for two operations in the event of failure of the central system.

The size and nature of the central compressor and storage plant will be determined by the number of breakers to be supplied, and the probable frequency of operation. The 500,000-kva breaker uses only about 15 cubic feet of free air per round trip operation. In one typical installation of these breakers, compressors rated 5 cubic feet per minute are used. These are operated by two-horsepower motors so with both the main and auxiliary compressors connected to operate, their running time will be about $1^1/_2$ minutes per breaker operation. Figure 5 shows this compressor and storage equipment, adequate for 12 500,000-kva breakers, for average central-station service. Two 5-cubic-feet-per-minute compressors are used, either one or both of which may be selected to hold the primary tank pressure automatically within selected limits.

For indoor service, the moisture content of the air is of concern only in so far as it might cause sticking of the valves, since it has no effect on the interrupting performance of this type of breaker. To secure the required degree of dryness in the air, therefore, this system compresses to 250 pounds pressure in the primary tank where the air is cooled, dropping most of the moisture content. An automatic reducing valve feeds the secondary tank at 150 pounds pressure with dry air, which has been found to have a dew point below zero degrees Fahrenheit, which is entirely safe for indoor service. In addition to the automatic pressure controls for the compressor motors, the usual water pumps, oil traps, and safety valves complete this part of the equipment.

Each individual breaker storage tank is equipped with a pressure switch, which at any predetermined low pressure can be arranged to perform one of three functions:

1. Sound an alarm
2. Trip the circuit breaker
3. Lock the breaker against tripping

The type of service on which the breaker is used, will generally determine which of the three alternatives should be selected. This switch is equipped with a manually operated by-pass, so that the operator may elect to trip the breaker to clear normal load current, which requires only very low air pressure, when the air in the tank might not be adequate for full interrupting rating performance.

Tests

A very comprehensive series of interrupting tests was brought to a climax in August 1939 by a demonstration of the 500,000-kva breaker to a large group of interested engineers, at the high-capacity testing station at Schenectady. The breaker was subjected to both opening and closing-opening tests over a range from 10 per cent to 150 per cent of interrupting rating. Table I summarizes the results of these tests, indicating that the longest arcing time was 0.5 cycle and the longest breaker operating time 6.0 cycles.

Table I. Three-Phase Tests at 14,500 Volts

		Current, Amperes Maximum Phase					
		Maximum Loop					
Test Number	Duty	Peak Value	RMS Value	Initial in Arc, RMS	Kva, Three Phase	Cycles From Trip Impulse to Interruption	Arc Length (Cycles)
1	O	4,400	2,800	2,100	53,000	5.0	0.05
2	O	12,000	7,000	5,400	135,000	5.4	0.1
3	O	32,000	19,500	13,500	340,000	5.0	0.05
4	O	48,000	29,000	19,000	480,000	5.8	0.2
5	O	55,000	32,000	25,000	630,000	5.9	0.3

7	CO	80,000	49,000	29,000	780,000	6.0	0.5

Table II

		Current, Amperes					
		Maximum Loop					
Test Number	Duty	Peak Value	RMS Value	Initial in Arc, RMS	Kva, Three Phase	Cycles From Trip Impulse to Interruption	Arc Length (Cycles)
1	CO	166,000 197,000 105,000	98,000 112,000 68,000	44,000 48,000 48,000	350,000	4.9	0.80 1.05 0.45
2	O	163,000	97,000	78,000		3.8	0.70

Additional tests were made on this same breaker following this series, making a total of some 20 operations, 13 of which were at or above full rating. Following this complete series, the contacts shown in figure 6 were still in condition to permit making many more tests without attention.

Figure 7 is a typical oscillogram taken during this series of tests, and shows a three-phase closing-opening operation at 27,000 amperes, 14,500 volts, or slightly above full rating of the circuit breaker.

One of the unique features of this type of interrupting device is its high current-closing ability. The blast of air during the closing operation effectively delays the striking of the arc until the contacts have practically touched, and then promptly clears away the gases which are generated. Table II, test 1, shows the results of a typical three-phase closing-opening test at 4,200 volts in which the breaker successfully closed against a peak current of 197,000 amperes and then tripped and cleared. Test 2 was an opening test at 4,200 volts across a single-pole unit, in which the breaker cleared a current of 78,000 rms amperes, initial in arc.

In the course of making tests for design information, at reduced pressure levels, or with experimental timing of blast-valve opening with respect to contact separation, occasional operations were encountered when the breaker did not clear, and in due course of time the fault was removed by the station back-up breaker. In such cases arcing continued within the interrupting chamber, melting contact parts, and destroying some of the material of the arc chute. However, no damage resulted to the cell or enclosing structure, either by disruptive forces or by arcing. In all cases the breaker was again ready for service inside of two hours after merely replacing contact parts and barriers.

Conclusions

Oilless circuit breakers for indoor service are now available for the first time in interrupting ratings completely covering the range of oil breaker ratings. A number of high-capacity units has been placed in service, and a 1,500,000-kva 15-kv triple-pole unit has been built and completely tested. A review of the design and tests on the air-blast breaker brings out the following:

1. Complete elimination of fire hazard
2. Positive operation, with arcing time closely approaching the irreducible minimum
3. Contacts and arcing compartment built for long life, and minimum deterioration
4. Arcing contact exposed for ease of inspection
5. Flexibility of mounting arrangement, permitting either bottom, back, or top connections
6. Space requirements equal to, or less than correspondingly rated oil breakers, which is of importance in modernization of old stations or extensions of existing switchhouses
7. Simplicity and compactness of application to steel cubicle construction, which is easy to install, safely interlocked, and having all design features co-ordinated
8. High inherent current-closing ability

ASSOCIATE AIEE

Synopsis: The demand for oilless circuit breakers of large interrupting capacity to meet the requirements of American practice directs attention toward an improved compressed-air circuit breaker which materially extends the present limitations as exemplified by continental designs.

A brief historical review of the trend toward oilless-circuit-breaker development is given. The comparison is made of the available methods of circuit interruption in air. The particular applicability of compressed air is stressed and a new circuit interrupter is described which can reach an interrupting capacity of 1,500,000 kva at 15,000 volts. Among the outstanding features of this interrupter are extremely high operating speed and rapid interruption with minimum energy dissipation. Test results are given indicating the adequacy of this type of design.

THE circuit-breaker art, almost from the time of its inception, has depended upon the use of oil as an interrupting medium in the larger and higher-voltage units. The choice of oil was based upon its excellent insulating properties and its remarkable arc-quenching ability. Oil, and its vapor, can be ignited, however, and thus can constitute a serious fire hazard, as the result of abnormal circuit-breaker operation. This factor has long been recognized, but practical operation of electrical systems has demonstrated that oil fires directly chargeable to circuit-breaker failures have been negligible. Recently, however, growing demand on the part of operators and development of the principles of oilless circuit interruption in Europe have combined to strengthen the interest in oilless circuit breakers in this country.

The first major contribution in the oilless breaker field was the development of the De-ion air breaker in 1928.[1, 2] Prior to this time, air circuit breakers had been used for many years with unquestionable success in lower-voltage circuits in which limited interrupting capacity was sufficient. The De-ion breaker, however, interrupted an arc in air using entirely new principles and so efficiently that it has been constructed for voltages up to 23 kv and for interrupting capacities as high as 750,000 kva at 15 kv or 1,500,000 kva at 23 kv. Twenty-three kv is sufficient for virtually all indoor applications in this country. This breaker is completely self-contained and operates without an auxiliary air system or the need of a replenishable interrupting fluid.

Greater interrupting capacities are continuously being required, and the economic range of the De-ion breaker will not prove adequate for all requirements. For higher interrupting capacities to 1,500,000 kva at 15 kv other forms of oilless breakers take on new attractions.

The departure from oil in Europe began with the introduction of both compressed-air and water breakers in 1929 and 1930.[3–6] The new trend was accelerated there because of the high price of oil and

metals and because the limited capacities for which compressed air or water circuit breakers could then be built were sufficient to meet European requirements. Considerable development has been done in Europe with both types of breakers. The field of application of oilless breakers in Europe is becoming extensive and for some manufacturers is including the higher voltage and outdoor types.[7-9] In America, by contrast, the immediate demand is limited to indoor oilless breakers and although the European developments may influence the American trend, the more limited interrupting capacities which they find acceptable will not be sufficient to meet our requirements. This is especially true since European designs do not reach 1,000,000 kva, and American practice requires 1,500,000 kva or more at generator voltage.

Comparison of Principles of Air Circuit Interruption

In choosing a suitable operating principle for application to air circuit interruption, an experimental review of available methods was made. The results of this review will be described to present the background of reasons for the choice of interrupter finally reached.

COMPRESSED-AIR ARC EXTINCTION

In Europe, variations of the nozzle type of interrupter have become most popular. They consist of an orifice through which an arc is drawn or blown and then subjected to a very intense longitudinal blast of air. For the lower ranges of current and at system capacities where the voltage recovery rate after arc extinction is not too great, this type of interrupter is quite satisfactory. As the current or voltage is increased the air requirements mount, until at 1,000,000 kva, pressures in excess of 200 pounds per square inch are required. The nozzle type of interrupter is, therefore, not appealing.

SELF-GENERATED-GAS-BLAST BREAKERS

In order to overcome the necessity of an external air-supply system, the blast of gas may be obtained by the decomposition of suitable materials. By selecting the proper material and arrangement, very high pressures of suitable gases may be obtained, and the energy to produce the gas pressure may be extracted from the arc itself during short circuit.

Boric-acid fuses and De-ion protector tubes are excellent examples of devices operating on this principle. In Europe, circuit breakers have been produced commercially where a synthetic resin is used for producing the gas blast.[13] Two self-generated-gas-blast breakers have been developed by the company with which the authors are associated—one utilizes boric-acid in close proximity to the arc-drawing contacts with suitable boric-acid-lined arc chutes into which the arc is driven by the expelled arc gases. The other is a two-arc interrupter as shown in figure 1. One arc is established through a conventional orifice and subjected to a longitudinal blast of gas in quite the same manner as used in continental compressed-air circuit breakers. The other arc is drawn in a space closely surrounded by gas-producing walls. This arc is not relied upon to supply interrupting ability except for low values of current, but to supply the gas blast for the first mentioned arc.

The interrupter consists of three essential elements—the lower part which houses one set of contacts, and the gas-forming elements; the central part which cools the hot gases and as a result of the

energy thus extracted, liberates more gas and eventually delivers the thoroughly cooled and deionized gas to the interrupting arc (which is located at the top of the interrupter) in such quantity and at sufficiently high pressure to handle very heavy currents.

* Magnetic oscillograms of these tests are shown in figure 6.

In this type of design the gas-forming parts must be shaped to supply sufficient gas for interruption at low currents without having excessive gas generation and pressure at high currents. Since the gas is obtained from solid surfaces in proximity to an arc, repeated operations produce erosion that affects the amount of gas generation and the interrupting characteristics. These considerations, together with other factors, discouraged further work on this type of construction.

The interrupter has handled currents up to 48,000 amperes at 7.6 kv and to 30,000 amperes at 13.2 kv as shown by the oscillogram in figure 2. The arcing time for the high values of current usually did not exceed two half cycles yet pressures as high as 1,000 pounds per square inch were recorded. While this pressure may seem high, extrapolation from compressed-air requirements for this type of nozzle interrupter are quite comparable. The ratings desired, however, appear to be beyond the capacity which can be reached with this principle.

MAGNETICALLY PRODUCED AIR BLAST

For many years magnetic fields have been used to extinguish arcs by blowing them into some type of arc chute which lengthens and constricts the arc. Recently a new means of effecting interruption with a magnetic field has been described.[3,4] An interrupter of this type consists of parallel insulating plates spaced apart and slotted at the lower end. The arc is driven into this slot by means of a magnetic field. When the arc reaches the upper portion of the slot the magnetic field exerts a force on the electrons in the gas stream and gives them a component of velocity transverse to the arc. These electrons in turn bombard neutral gas particles, with the final result that a blast of gas is caused to flow upward through the arc path. When current zero is reached this blast of gas effectively introduces a strong deionizing action at the end of the slot, which effectively extinguishes the arc.

Within the last two years two types of lower-voltage breakers have been developed using this interrupting principle. The first type was for 600 volts and below and the second for potentials of 2,500 and 5,000 volts. The lower-voltage devices have interrupted currents as high as 120,000 amperes and the 2,500-volt interrupter satisfactorily clears currents up to 50,000 amperes.

The effectiveness of this principle is not sufficient for the interruption of currents as high as 60,000 amperes at 15,000 volts.

Compressed-Air Interrupter

A more effective air stream can obviously be produced by utilizing compressed

air in the type of arc chamber just described. In this case the magnetic field is no longer necessary. Tests were made with this structure which indicated greatly increased interrupting capacity. An external air-supply system must be provided of course, but in view of the extremely high interrupting ratings which can be achieved in very small space, the use of compressed air in conjunction with an arc chamber of the type described appeared to be the most feasible method of proceeding toward the design of a breaker having sufficient interrupting capacity to meet all indoor requirements. A comparison of the interrupting ability of a compressed-air device built in this manner, with known types of compressed-air breakers utilizing nozzles for interruption, indicated that an air stream perpendicular to the arc path in conjunction with insulating plates was much superior.

The contacts and surrounding walls are arranged so that the arc is blown by the air stream from its point of inception against suitable insulating splitters. There the arc remains practically stationary and substantially perpendicular to the gas blast throughout the arcing period. During this time the gas is allowed to escape around the sides of the arc, freely enough to prevent building up of pressure sufficient to interfere with the continuity of the arc stream and at the same time sweeps the excess ionization from around the arc out into the space beyond the splitters. Thus, as the current zero approaches, the residual ionization associated with previous high current has been removed without high arc voltage, and the time between current zero and restored voltage becomes adequate for interruption even though the voltage recovery rate is high.

The next important requirement is to cool and deionize the gases sufficiently before allowing them to escape beyond the splitters, to prevent flashover on the outside. Further cooling is necessary for the higher kilovolt-ampere ratings to prevent excessive external demonstration. Both of these problems are solved by suitable coolers and mufflers described later.

Aside from the considerations of intimate association of the gas pressure, arc behavior, and splitter performance, there are other practical reasons that favor the cross-blast type of construction over the longitudinal blast. These considerations are: (1) the ability with a blast of air directed at right angles to the direction of contact separation to sweep the arc quickly from the contacts, thereby permitting both main and arcing contacts to remain in the chute; (2) the ability to increase the cross-sectional area of the main current-carrying member within wide limits, without affecting any of the parts

involved in arc extinction. These two factors simplify the construction of the breaker and are of particular importance on the heavier current units of the powerhouse class.

An experimental arc chute as shown in figure 3 was built along these lines for test. This form of interrupter is flexible and can be adapted to a breaker design as shown in figure 4, or it can be disposed horizontally, depending on the application requirements. Figure 5 shows an open view of this same chute after having successfully interrupted 45 short circuits at currents varying from 1,000 to 50,000 amperes at 13,200 volts as listed in table III. During the tests the interrupter was in a horizontal position on the breaker. After these tests the contacts were found to be in excellent condition. There was some erosion of the splitters as may be seen, however, this erosion was not sufficient to render them unfit for further service.

Referring to figure 5, (1) is the stationary contact from which the moving contact (2) is withdrawn pulling an arc along the path (3). This arc under the action of a blast of air from the orifice (4) is driven into intimate contact with the splitters (5) along the path (6). The arc gases expelled from the throat impinge first on the copper buffer plates (7) which perform the first cooling and deionizing action on the arc gases. The partially cooled and deionized gases then pass on through the cooling and diffusing screens (8) that cool and diffuse the arc gases effectively preventing external flame and disturbance.

Test Results

Tables I, II, and III show the results of three typical series of single-phase tests using the arc chute shown in figure 3. During these tests the pressure in the tank varied between 105 and 150 pounds per square inch. The pressure in the arc chute was measured with an instantaneous recording telemeter. This pressure was negligible except during the arcing period. The effect of the arc acting as an impediment to the free escape of air caused a temporary build-up in pressure back of the arc which in some cases almost equalled the tank pressure.

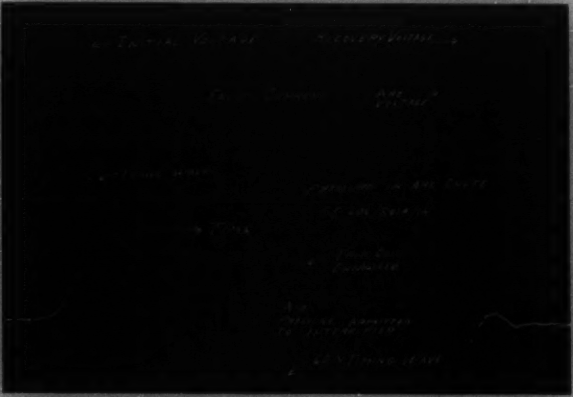
The arcing time was generally less than that corresponding to one-half cycle of current. Sometimes when the current was highly asymmetrical arcing would continue over one entire current loop which would lengthen the time to over one-half cycle. The breaker rarely passed up an opportunity to clear if the contacts were parted one-half inch or more when a current zero occurred.

Tables I and II show currents ranging from approximately 1,000 amperes to 52,000 amperes with 13.2 kv across a single-pole unit.

Figure 6 shows typical oscillograms taken from table I at 1,000, 12,700, 35,000, 48,000, and 53,000 respectively. The oscillograms from table II are all very similar to the ones shown in figure 6.

Table III shows a series of 45 tests covering the same current range. On some of these tests cathode-ray oscillograms were obtained, these together with the magnetic oscillograms shown in figures 7 and 8 are of interest in proving that the operation of the breaker is consistently fast and dependable even on a circuit with a natural oscillatory frequency of 28,300

Figure 9. Typical oscillogram of closing-opening tests



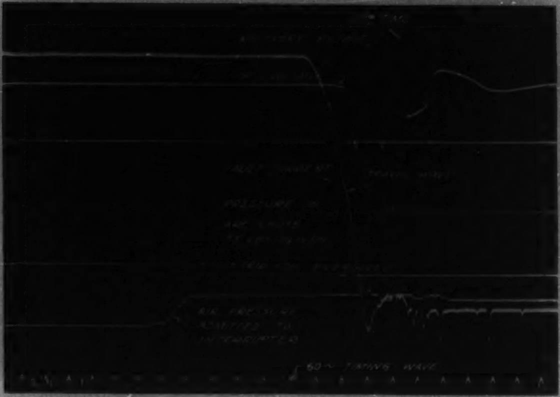


Figure 10. Oscillogram showing interruption of 65,300 rms amperes at 13.2 kv, single phase

cycles per second, and a circuit transient recovery voltage rate of 2,200 volts per microsecond. On this circuit the test transient recovery voltage rate was 1,380 volts per microsecond as shown for test 19. The transient recovery voltage rate is given as the slope of the tangent to the recovery voltage wave. It is obtained by dividing the maximum voltage by the time of one-half cycle of natural frequency and multiplying by 1.15. This method is used because the recovery transient consists essentially of a single sinusoidal component.

Figure 9 shows a typical closing-opening test. The ability of this breaker to close in on high current without showing any evidence of distress is noteworthy.

Figure 10 shows an oscillogram of the highest current interrupted. It was obtained during a fourth run similar to the one shown in the tables. This film shows satisfactory interruption of 65,300 amperes rms at 13.2 kv, single phase.

These interruptions were obtained with negligible external demonstration in the form of ionized flame. Noise accompanying the interruption is held to acceptable limits by the arc chamber design as shown. A particularly significant feature of all tests is the high mechanical speed of the breaker contacts. It is possible to separate these contacts two inches in one-half cycle. This high speed is the effect of properly using an air mechanism to operate the breaker. Very high opening and closing forces can be exerted on the piston which is moved in the cylinder by the compressed air itself to actuate the contacts. Springs which would give comparable operating speeds would represent a nearly impossible mechanical design. It is also a simple matter properly to control the air cylinders to stop the contacts and their associated operating rods without undue jar on rebound at the end of the opening stroke.

A compressed-air interrupter of the type described appears to be particularly rugged and to handle repeatedly interruption of the highest currents without excessive damage. The low energy input into an interrupting chamber of this type which is the function of careful design to minimize the arcing time, to approximately one-half cycle, and to keep the arc drop low during the arcing period, is primarily responsible for reliability without excessive erosion.

*19	28,300	21,400	1,380	2,200

* Magnetic oscillograms and cathode-ray oscillograms of these tests are shown in figures 7 and 8 respectively.

Conclusions

The search for improved forms of dry-type circuit interrupters suitable for interruption of 1,500,000 kva, at 15,000 volts, indicates that the use of a compressed-air stream transverse to an arc is the most effective. Currents as high as 65,300 amperes have been interrupted at 13,200 volts single phase with a contact separation of approximately two inches, which can be mechanically obtained in one-half cycle. A breaker utilizing these new principles of interruption makes possible new standards of system protection because of its high operating speed, complete freedom from oil and associated fire hazard, and remarkably high interrupting capacity in terms of the space required by the breaker.

Discussion

Discussion will be found in the 1940 annual TRANSACTIONS volume and in the 1940 "Transactions Supplement" to ELECTRICAL ENGINEERING.

What Wood May Add to Primary Insulation for Withstanding Lightning

J. T. LUSIGNAN, JR.
MEMBER AIEE

C. J. MILLER, JR.
ASSOCIATE AIEE

ON power-transmission lines, wood, serving certain structural functions, simultaneously may provide supplementary insulation against lightning if properly chosen and applied. However, to sustain the power-frequency voltage, adequate primary insulation in the form of porcelain insulators or the like is essential.

These facts have been rather well known for some time, but in degree the ability of wood to withstand lightning has not been thoroughly determined. In the laboratory study described two years ago,[1] this phase was partially covered. It is the purpose of this paper to describe the results of a testing program in the same laboratory, treating of all factors which it was felt could affect the lightning or impulse strength of wood.

Nothing relating to the 60-cycle strength of wood will be given here, for, as outdoor insulation against sustained power-frequency voltage, wood, with its internal moisture, is generally considered quite ineffective. For briefly applied surges, such as lightning or switching transients below flashover voltage, the moisture content is not damaging to the wood. However, for sustained 60-cycle voltages, the electrolytic nature of the moisture allows leakage currents which ultimately cause burning and charring of the wood. As intimated above, it is the purpose of effective primary insulation in series with the wood to check this action.

It will be shown below that the degree to which wood will supplement porcelain against lightning depends almost entirely upon its length and internal moisture, and little upon its creosoting treatment, cross section, or kind. Considerable test data were obtained in this study and numerous curves and tables developed directly therefrom. In the interest of brevity and clarity, practically all of these original curves are omitted here and only so-called "working curves" which were derived from the originals, are included. Accordingly, most of the kilovolts of insulation plotted involve actual supplementary wood insulation values to be added directly to the impulse kilovolts of the associated insulators. Likewise, ratios and percentages are used for expressing the effects of certain wood properties upon the insulation strength of wood.

Nature of Test Equipment and Data

The various stages of the 3,000,000-volt impulse generator at the Barberton high-voltage laboratory of the Ohio Brass Company were used in these tests. The generator itself was always adjusted for the standard $1^1/_2$x40-microsecond wave.

For tests on the wood specimens alone, voltage was applied between braided metallic bands tightly wrapped about the wood. This was felt to simulate electrically most hardware conditions in service. In the case of a combined insulator and wood test, voltage was applied to the conductor attached to the insulator while the braided band was adjusted along the wood member and grounded. For all tests, the specimens themselves were suspended at sufficient distances from nearby grounded objects to eliminate interference with the electrostatic fields being studied.

On practically all specimens, complete volt-time curves were taken with both positive and negative polarities, cathode-ray oscillograms being secured for every impulse. To allow compactness of presentation, however, curves are given showing flashover voltages at only the two-microsecond and "critical" (formerly termed "50-50" or "minimum") points. It is felt that the two-microsecond point represents direct-stroke conditions of average severity while the critical flashover values allow computations for induced voltages and other long-wave conditions.

Flashover Voltages of Structure Parts

As pointed out above, any structure design computations made from information in this paper require the addition of the supplementary wood values from certain curves to actual insulator flashover values. Figures 1 and 2 provide the necessary flashover data of a pin-type and a suspension insulator for use in typical examples in this paper.

Figure 3 affords rod-gap data for assisting in designing so-called "horn gaps" for wood members. As will be shown by later examples, such gaps can be made to protect parallel crossarm or pole paths if adjusted to have lower flashover strengths. The proper crossarm and pole data for this comparative study is provided in the curves of figures 4 and 5. No measurable difference was found for surges of the two polarities so that the curves of these two figures represent the average of all data. The data from figures 4 and 5 are only for comparison with other parallel flashover paths, such as air gaps or insulators, and they are not to be added to other insulation in series.

Flashover Voltages Added to Porcelain by Wood

In figures 6 to 9 are given the supplementary impulse insulation strengths afforded porcelain insulators by different lengths of various wood members. For each case the flashover data from the curve *must be added* to the corresponding flashover data of the insulator chosen in order to have the total lightning or impulse strength of the combination. The supplementary insulation values which

Paper 40-25, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 8, 1939; made available for preprinting December 14, 1939.

J. T. LUSIGNAN, JR., is executive engineer with the Ohio Brass Company at Mansfield; C. J. MILLER, JR., is electrical engineer with the same company at Barberton, Ohio.

Crossarm and pole specimens used in many of the tests were from the Georgia Power Company, Mississippi Power Company, New England Power Service Corporation, and Ohio Power Company. The special creosoted planks with known moisture contents were prepared by the Wood Preserving Corporation under the direction of W. P. Arnold.

[1] For numbered reference, see end of paper.

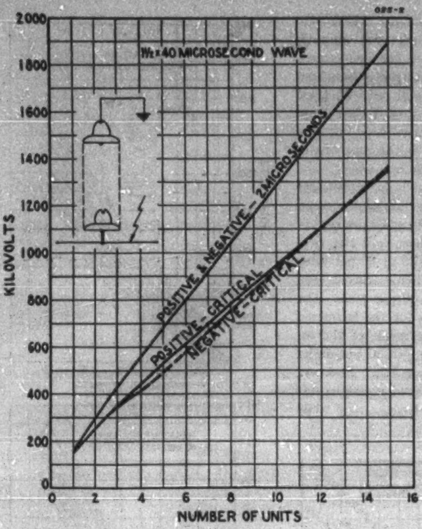

Figure 2. Impulse flashover voltages of 10 by 5$^3/_4$-inch suspension insulators

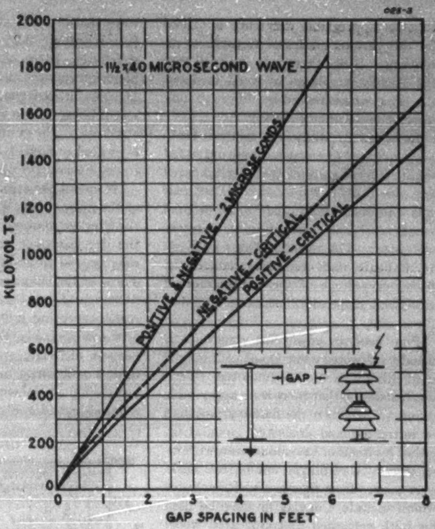

Figure 3. Impulse flashover voltages of rod gaps

pole sections add to pin-type crossarm combinations (figure 6) are shown in figure 10.

All wood insulation values in figures 4 to 10 inclusive, except for cedar and newly creosoted pine poles in figure 5, are based on tests on wood with an average moisture content of about 15 per cent.

Data, described in the paper referred to above,[1] indicated that the total insulation strengths of insulator and wood combinations could be calculated by multiplying the sum of the individual flashover strengths by certain constants. Subsequent and more numerous data, however, tend to prove that more accurate calculations can be made by the use of curves such as given in figures 6 to 10. Also, an analysis of the electrostatic conditions involved tends to bear this out. For example, the effect of changing the constants of one member, such as by lengthening indefinitely the crossarm supporting the insulator, cannot always allow the actual flashover voltage to be the same percentage of the sum of the insulator and arm flashover voltages.

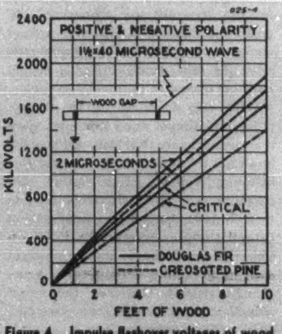

Figure 4. Impulse flashover voltages of wood crossarms

Factors Influencing Impulse Insulation Values

Cross Section

Previously published data[1] indicated that the impulse flashover voltage of wood decreases as its cross-sectional area is increased. This subsequent investigation, however, shows that certain other factors have greater effects and that cross-sectional area is of secondary importance.

Another related factor which may affect the flashover voltage is the distribution of the wood cross section, as exemplified by solid and multiple-plank crossarms with equal cross-sectional areas. The ratios in figure 11 are the result of flashover tests upon a number of combinations of insulators and creosoted pine timbers. The latter were first tested as six by eight-inch solid crossarms and then sawed and retested as three by eight-inch double plank crossarms. The average ratio for the positive critical flashover is about 0.96 and that for the negative is about 1.02, indicating that as far as the impulse flashover voltage is concerned, there is little to be gained by the choice of one type of construction over the other. However, a definite advantage is gained with the double-plank crossarm in that a lightning stroke damages only one member and leaves the other intact for supporting the line.

Creosote Treatment

Since wood used in power-line structures may be creosoted, it is desirable to know the effects on flashover voltages of the various kinds of creosote, degrees of retention, and methods of treatment. A number of flashover tests were made on three-foot sections of newly creosoted green pine crossarms in series with three 10 by 5$^3/_4$-inch suspension insulators. Light creosote with retentions of eight and ten pounds per cubic foot of wood, and heavy creosote with a ten-pound retention were used in the preparation of the test specimens. Results of these tests, some of which are shown in figure 12, indicate that no appreciable difference is caused by the various grades of creosote or retentions. Still other tests indicate that the flashover voltage of wood is about the same when treated by different commercial creosoting processes.

In order to study the relative flashover voltages of creosoted and untreated wood, several pairs of specially prepared dry pine timbers were tested. Each pair was obtained from the same original plank, and only one of each pair was creosoted. The results, shown in figure 13, indicate that creosoting reduces the flashover voltage of the combination of wood and suspension insulators only 6 or 7 per cent.

Pine used in power-line structures is usually creosoted while Douglas fir may be used either untreated or creosoted. Various tests show that there is no appreciable difference between the flashover voltages of untreated and creosoted Douglas fir, either by itself or in combination with insulators. Accordingly, all of the flashover curves from figures 4 to 10 inclusive which include Douglas fir may be used for both creosoted and untreated wood.

RAIN

Since lightning is usually accompanied by rain, it seemed desirable to know the effects of rain on the impulse insulation of wood. It had been reported previously[1] that rain may reduce the impulse flashover of wood structures by as much as 50 per cent.

In order to determine whether such a reduction is caused by rain in the air, and on the insulator and wood surfaces, or by the moisture penetration into the wood, a special series of tests was made. A dry Douglas-fir crossarm was completely covered with several coats of lacquer to keep out moisture and subjected to dry and wet flashover tests. The wet tests were made using standard AIEE rain (precipitation 0.2 inch per minute; resistivity, 7,000 ohms per inch cube). Similar tests were made upon unlacquered Douglas fir, red elm, and red oak, these woods being chosen because of their dense structure. The results of these tests are presented in figure 14 as the ratio of wet to dry flashover voltage.

As shown, the critical flashover voltages of the unlacquered woods are reduced on the average to about 65 or 70 per cent of the dry flashover values, and the two-microsecond to about 75 or 80 per cent. Those of the lacquered crossarms showed a change of less than 10 per cent. The ratios exceeding unity for the lacquered arm are probably the result of the increased dielectric strength of air under rain conditions. Since the flashover value of each unlacquered crossarm was reduced considerably by the rain while that of the lacquered arm was practically unchanged, it seems logical to presume that the penetration of moisture into the wood is the fundamental cause of the observed reduction.

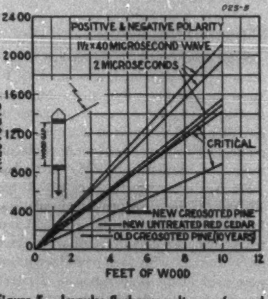

Figure 5. Impulse flashover voltages of wood poles

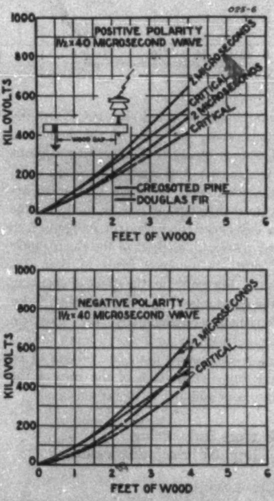

Figure 6. Impulse insulation added to pin-type insulators by crossarms

The effect which the duration of rain has upon the impulse insulation of wood and insulators is indicated in figure 15. The tests here were made on four-unit insulator strings suspended from four-foot sections of both untreated Douglas-fir and creosoted-pine crossarms. The greatest reduction in flashover voltage seems to occur within a very few minutes after the rain starts, negligible change resulting thereafter.

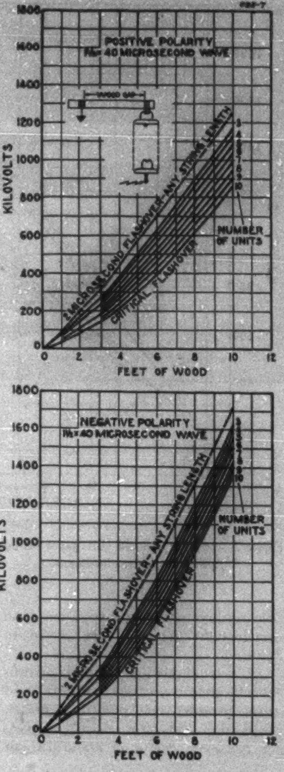

Figure 7. Impulse insulation added to suspension-insulator strings by wood crossarms (creosoted pine or Douglas fir)

While rain definitely reduces the impulse insulation of wood structures, there is always a chance that the wood may not be wet at the instant it is subjected to a lightning voltage. Furthermore, the standard rate of precipitation used in these tests far exceeds the usual rate of natural storms. Accordingly, it is possible that the flashover voltage may not decrease as rapidly as indicated in figure 15. In general, therefore, the actual reduction factor for rain for a given condition appears to be a matter of probability.

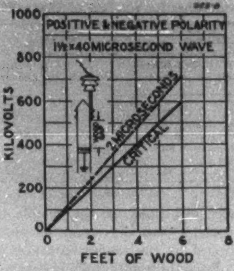

Figure 8. Impulse insulation added to pin-type insulator by pole sections (creosoted pine)

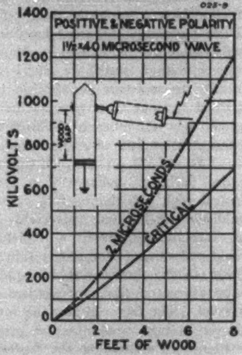

Figure 9. Impulse insulation added to suspension-insulator strings by pole sections (creosoted pine)

Moisture Content

The results of the various rain tests indicated that moisture penetration into the wood was responsible for the reduction of its impulse flashover voltage. Furthermore, it had been observed that green wood has a lower flashover voltage than equivalent dry wood. Accordingly, it seemed desirable to conduct a systematic investigation of the effects of internal moisture upon the impulse flashover voltage of wood.

Figure 16 gives results of flashover tests on four-unit strings of 10 by $5^3/_4$-inch insulators suspended from four-foot sections of creosoted-pine crossarms with moisture contents varying from 12 to 93 per cent. Similar tests were made on the same crossarms without insulators. Other tests were also made on similar arrangements of untreated Douglas-fir crossarms with controlled moisture contents.

The results of this study are presented in figure 17 as the ratio of the flashover voltage at any moisture content to the flashover voltage at 15 per cent moisture content. The latter is usually considered the average for dry wood in moisture equilibrium with the atmosphere.

When wood with internal moisture is placed under electrical stress, electrolytic conduction may occur within it. This might influence the electrostatic field of the wood, and therefore, its flashover voltage in combinations with insulators. The degree to which this would take place may vary with the different woods because of their internal cellular structures. This may account for the difference in behavior of the several woods in the curves of this paper. The amount of voltage reduction introduced by internal moisture also may be dependent upon the duration of the transient, as time is required for electrolytic conduction. This may be a possible explanation of why the two-microsecond flashover voltage (figure 17) is influenced less than the critical by the internal moisture.

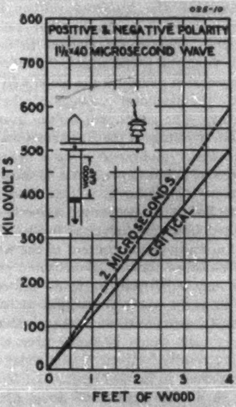

Figure 10. Impulse insulation added to combinations of pin type with crossarm by sections of poles (creosoted pine)

From figure 5, the critical flashover voltage of eight-foot sections of newly creosoted pine poles is about 720 kv while that of old poles is about 1,200 kv. The ratio of these flashover voltages is about 0.60, which corresponds to a moisture content of about 33 per cent on the creosoted pine curve in figure 17. The newly creosoted pine poles were presumably green wood while the old poles were fairly dry, having been in service for several years. A moisture content of 33 per cent is a reasonable value for green wood and, accordingly, it would seem that the curves shown for crossarms (figure 17) may be satisfactory for poles as well.

As shown by the curves of figure 17, an immediate increase of impulse insulation strength may be secured by predrying wood to its equilibrium value before it is installed on transmission-line structures. On the other hand, the insulation value of green wood will increase gradually to the same level as its internal moisture approaches equilibrium with that of the atmosphere. Accordingly, the choice between predried and green wood appears to be a matter of economics.

Spread of Data

All curves presented in figures 4 to 10 inclusive represent the average of numerous data points, which lie within ±15 to ±20 per cent of the average. These rather wide limits are believed to be the result of inherent structural variations within the wood itself which influence its impulse flashover voltage.

Critical flashover tests were made on a group of about 60 newly creosoted pine poles, each pole being subjected to the same test procedure. These flashover voltages ranged from 490 kv to 836 kv, averaging about 675 kv. The spread of data with respect to the average was as follows:

Spread of Data in Per Cent	Number of Test Values Included	Per Cent of Total Number of Test Values Included
± 5	25	41
±10	41	67
±15	48	79
±20	56	92
±25	60	98
±28	61	100

In the above table 92 per cent of all

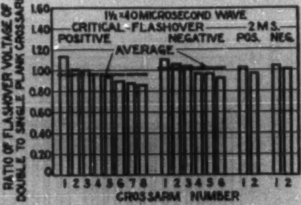

Figure 11. Comparison of impulse flashover voltages of single- and double-plank crossarms with pin-type and suspension insulators

Table I. Protective Horn Gaps on Creosoted Pine Crossarms for Six Feet of Green Wood

	Positive		Negative	
	Critical	Two-Microsecond	Critical	Two-Microsecond
Flashover of dry wood (figure 4) in kv	840	1,080	840	1,080
Assumed moisture content in per cent	35	35	35	35
Reduction factor (figure 17)	0.57	0.77	0.57	0.77
Flashover of green wood in kv	480	830	480	830
Rod gap having flashover equal to that of green wood (figure 8) in inches	0.29	832	25	32

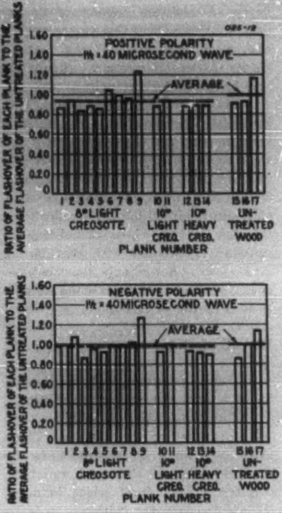

Figure 12. Effects of various creosotes and retentions upon impulse flashover voltages of pine crossarms with suspension-insulator strings

the tests are included in a ±20 per cent spread while a ±25 per cent spread includes all but one test. Similar distributions of test values would probably be found for various combinations of insulators and wood, although the spread in the above tabulation of green-pole data is probably as great as would ever be found.

When the curves of figures 4 to 10 inclusive are used for estimating the flashover voltage of a given structure, the result obtained will represent the average flashover voltage of a large number of similar structures. For example, if tests were made on 100 similar structures the average of these test values would probably agree quite closely with the estimated average and 90 to 95 per cent of these tests would lie within a ±20 per cent band.

Application of Curves to Typical Problems

General Procedure

By means of the curves in this paper it is possible to estimate the various impulse flashover voltages of numerous combinations of insulators and wood.

The first step is to obtain the flashover voltage of the insulator, either from figures 1 or 2 or from other reliable sources. The second step is to determine from the proper curve the kilovolts of insulation *added* by the wood and *add* it to the flashover voltage of the insulator. The result will be the average flashover voltage of the given combination of insulator and wood with a moisture content of about 15 per cent. If the wood is green, this flashover voltage should be multiplied by the proper reduction factor, selected from the curves of figure 17 for the known moisture content of the wood. The moisture content of creosoted green pine may vary from 30 to 60 per cent, and in cases where the actual moisture content is unknown, an average value of 35 per cent would probably give satisfactory results. Green fir and cedar can be expected to be no higher than 35 per cent in moisture content. Incidentally, this may account for the flashover voltage curve of new cedar poles in figure 5 being higher than that of new creosoted pine poles.

In case the flashover voltage under rain conditions is desired, the flashover voltage, estimated for the combination of insulator and dry wood, should be multiplied by the proper reduction factor. From the results presented in figures 14 and 15, it would appear that a factor of 0.65 to 0.70 for critical flashovers and 0.75 to 0.80 for two-microsecond flashovers of either polarity would be suitable reduction factors due to the rain.

Tests previously discussed have indicated that the reduction in impulse flashover voltage caused by rain is due primarily to moisture penetration into the wood and not to a reduction in the impulse flashover voltage of the insulators or the surrounding air. Therefore, it seems a reasonable presumption that the impulse flashover voltage of a green crossarm with a high moisture content should not be lowered appreciably by rain. Accordingly, both a moisture-content reduction factor and a rain reduction factor should not be applied to the estimated flashover voltage for dry wood. The factor giving the lower flashover voltage would be the proper one to use in estimating the flashover voltage under adverse conditions.

Examples

The following examples are presented to illustrate several applications of the curves in this paper and to demonstrate the agreement of estimated with actual test values.

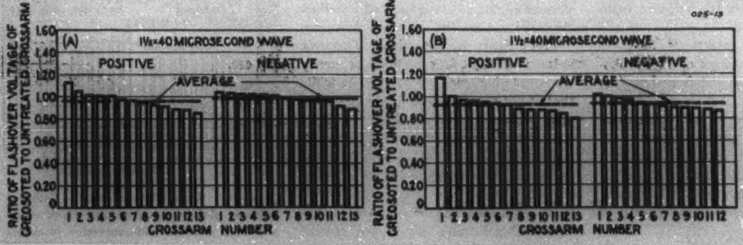

Figure 13. Effect of creosote treatment of wood upon its impulse flashover voltage with and without insulators

(*A*)—Five feet of creosoted pine crossarm only

(*B*)—Five feet of creosoted pine crossarm with five 10 by $5^3/_4$-inch suspension insulators

Example 1. In this example the dry and wet impulse flashover voltages of a 69-kv pin-type insulator and four feet of creosoted pine crossarm are determined.

Positive Critical

Flashover of insulator (figure 1)	260 kv
Insulation added by wood (figure 6)	410 kv
Estimated flashover, dry	670 kv
Actual test value, dry	690 kv
Ratio of estimated to actual	0.99
Reduction factor due to rain	0.65
Estimated flashover, wet	435 kv
Actual test value, wet	445 kv
Ratio of estimated to actual	0.98

The negative critical, and positive and negative two-microsecond flashover voltages may be estimated in a similar manner.

Example 2. In this example the estimated voltage is for phase-to-phase flashover between conductors supported by two 33-kv pin-type insulators on the same 22-inch creosoted pine crossarm with two wood sections between phases such as results from the use of metal crossarm braces. When an impulse is applied between conductors, each combination of insulator and wood section is subjected to an impulse of opposite polarity from the other. Accordingly, the procedure is to estimate the positive and negative critical flashover voltages for one insulator and wood section, add these two estimates together, and multiply by a factor of 0.85. The latter is chosen because tests have indicated that when two such combinations are placed in series the resulting flashover voltage averages about 0.85 of the sum of the flashover voltages of the individual combinations. Similarly, a factor of 1.00 has been determined for the two-microsecond flashover. There is evidence that the same procedure will prove satisfactory for strings of suspension insulators in place of pin type.

Critical Flashover

Positive critical flashover of pin type	200 kv	
Insulation added by wood (figure 6)	165 kv	
Total, positive		365 kv
Negative critical flashover of pin type	255 kv	
Insulation added by wood (figure 6)	130 kv	
Total, negative		385 kv
Sum, positive and negative		750 kv
Reduction factor	0.85	
Estimated flashover, positive or negative	640 kv	
Actual test value, positive	620 kv	
Ratio of estimated to actual, positive	1.03	
Actual test value, negative	650 kv	
Ratio of estimated to actual, negative	0.98	

The method of estimating used in this example naturally gives the same value for both polarities and actual tests indicate that there is little difference between the positive and negative flashover voltages of this combination of wood and insulators.

Example 3. In order to avoid shattering of crossarms when struck by lightning, parallel horn gaps are sometimes used which have shorter spacings than the sections of wood being protected. The intention is to have the flashover voltage of the horn gap somewhat lower than that of the wood in parallel with it, so that flashover will occur over the gap and not along or in the wood.

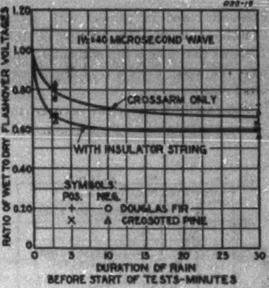

Figure 15. Effect of standard AIEE rain duration on critical impulse flashover voltage of suspension-insulator string and wood crossarm

Using the rod gap curves of figure 3 and the crossarm curves of figure 4, it is possible to estimate horn-gap spacings which will protect wood. Table I illustrates how such an estimate is made.

To protect the crossarm, it is evident that a 25-inch gap would be the longest permissible. In a series of tests run on six-foot sections of four creosoted pine crossarms, the protective gaps were found to be 24, 24, 25, and 27 inches, which are in good agreement with the above estimates.

Example 4. Horn gaps are occasionally used on poles in series with the down-lead to increase the impulse insulation of the pole top with respect to ground. A single pole gap with a 30-inch spacing is oc-

A—Douglas fir, lacquered, test 1
B—Douglas fir, lacquered, test 2
C—Red elm, untreated, test 1
D—Red elm, untreated, test 2
E—Red oak, untreated, test 1
F—Red oak, untreated, test 2
G—Douglas fir, untreated, test 1

Test 1—Four feet of wood plus a four-unit string of 10 by 5¾-inch suspension insulators

Test 2—Four feet of wood plus one 69-kv pin-type insulator

Figure 14. Effects of rain upon impulse flashover voltages of combinations of wood and insulators

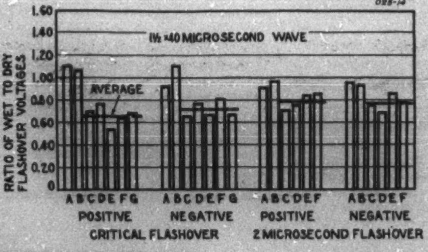

Figure 16. Effects of moisture contents of wood upon impulse flashover voltages of wood crossarms with suspension-insulator strings

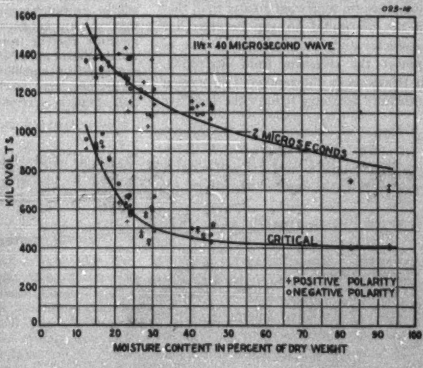

casionally used in parallel with about 94 inches of wood. The example in table II shows that such a gap adequately protects the wood, even if it is newly creosoted pine.

The excellent agreement between the actual test values and the flashover voltage of the equivalent rod gap indicates that rod gap curves may be used for estimating horn-gap flashover voltages with a fair degree of accuracy.

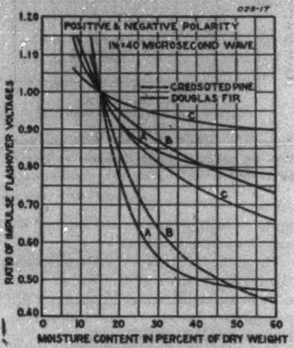

Figure 17. Ratio of impulse flashover voltages for various moisture contents relative to 15 per cent moisture

A—Critical flashovers, crossarms with suspension insulator strings

B—Critical flashovers, crossarms alone

C—Two-microsecond flashovers, crossarms alone or crossarms with suspension insulator strings

Example 5. In H-frame wood structures it is sometimes desirable to have the flashover voltage of the insulator string and crossarm somewhat greater than that of the horizontal air gap between line conductor and down-lead on the pole to protect the crossarm from shattering. In this example, the number of suspension insulators necessary to force the flashover to occur on the horizontal gap is determined (table III).

Table II. Thirty-Inch Protective Pole Gaps on 94 Inches of Newly Creosoted Green-Pine Poles

	Positive		Negative	
	Critical	Two-Microsecond	Critical	Two-Microsecond
Flashover of 94 inches of pole (figure 5) in kv	700	1,200	700	1,200
Flashover of 30-inch rod gap (figure 3) in kv	500	770	570	770
Actual test value in kv	485		570	

Table III. Required Number of Suspension Insulators on Six Feet of Creosoted Pine Crossarm to Force Flashover on Six-Foot Air Gap to Down-Lead

	Positive		Negative	
	Critical	Two-Microsecond	Critical	Two-Microsecond
Flashover of six-foot rod gap (figure 3) in kv	1,120	1,850	1,270	1,850
Flashover of crossarm with the following number of suspension insulators (figures 2 and 7) in kv:				
6 insulators	1,130	1,510	1,300	1,720
7 insulators	1,190	1,630	1,350	1,840
8 insulators	1,230	1,750	1,410	1,960
9 insulators	1,280	1,870	1,460	2,080
10 insulators	1,340	1,990	1,520	2,200

From table III, it is evident that the nine-unit insulator string is the shortest causing flashover voltages higher than all corresponding voltages of the rod gap. Accordingly, it should be expected to give the desired crossarm protection. In a series of actual tests on creosoted pine crossarms, a ten-unit string was required to cause flashover along the desired path.

Conclusions

1. Properly selected and controlled wood may add appreciably to the lightning insulation of a line. The magnitude is more or less in proportion to the wood length and may be estimated from curves presented in this paper.

2. Almost without exception, the lower the moisture content of wood the higher will be its supplementary lightning insulation value; in particular, reducing the moisture content from an average green-wood value of about 35 per cent to an average moisture equilibrium value of about 15 per cent may nearly double the insulation strength of creosoted pine structures, and raise that of fir structures by about one-fourth. The increase for various moisture contents may be estimated from figure 17.

3. During a rain storm, the lightning insulation strength of structures utilizing wood as supplementary insulation may suffer reductions to as low as 65 per cent of the dry flashover voltage within two or three minutes after the start of rainfall; further reduction, with continuation of the rain, is inappreciable.

4. The supplementary lightning insulation strength of wood is not appreciably altered by the grade of creosote, degree of retention, or creosoting process used in its treatment.

Analysis of Bushing-Current-Transformer Performance

J. P. GEBELEIN
NONMEMBER AIEE

J. A. ELZI
MEMBER AIEE

Synopsis: This paper is a presentation and discussion of the more important results obtained in a series of extensive tests made on bushing current transformers. In addition to the determination of the ratio and phase-angle characteristics, tests were made to determine the division of current in interconnected secondary circuits for conditions simulating actual faults in the primary circuit. It is also shown that most of the results obtained from the tests may be readily calculated from the excitation-current data.

IN the application of protective relays for transmission and high-voltage distribution substations, it is vitally important to give careful consideration to the ratio and phase-angle characteristics of the bushing current transformers used as accessory equipment. This has long been recognized, but the necessity for a wider scope of understanding of these factors and more information as to the methods of taking them into account has increased during recent years on account of the performance requirements of modern relaying schemes designed to provide more effective assurance of uninterrupted service. Furthermore, where there are multiple interconnected secondary circuits with totalizing phase and residual burdens such as result, for example, in a bus differential scheme of protection, there is the additional problem of determining the current distribution in the various branches of the secondary circuit for both balanced and unbalanced fault conditions.

The manner in which the ratio and phase relations of the secondary current to the primary current are affected by the components of current required for the excitation of the core and to supply the losses for steady-state conditions is well known,[1] but it is necessary for design and operating engineers to have more complete data than heretofore available, and to be provided with suitable methods of calculating the over-all performance under various conditions which may exist in the field. Similar information is also required regarding the performance during transient conditions but this phase of the problem is beyond the scope of this paper.

In order to obtain the necessary data regarding the performance of a particular relaying scheme, a series of extensive laboratory tests was made on a specific type of multiratio bushing current transformer for various secondary conditions. The purpose of this paper is, first, to present the more important results of these tests, and second, to show that the results so obtained can be calculated with reasonable accuracy from the in-phase and quadrature components of the excitation curves.

Some information regarding the wave-shape distortion of the secondary current by reason of the excitation component was also obtained and data regarding this phase of the tests are given in this paper.

Description of Transformers and Classification of Tests

The current transformers upon which the tests were conducted are quite similar in design to those in general use, consisting of a circular laminated core of silicon steel, a secondary winding with taps for different turn ratios, and a single-turn primary formed by the stud of the oil circuit breaker passing through the center of the core. By proper selection of the taps, turn ratios from 10 to 1 up to 120 to 1, with the exception of 70 to 1 and 110 to 1, may be obtained. In order to obtain better operating characteristics, these transformers were designed specifically to have larger core volumes than had previously been used.

For the purpose of this paper, the tests that were made may be classified and briefly outlined as follows:

(*a*). Ratio and phase-angle tests for different turn ratios and burdens.

(*b*). Single-circuit tests to determine the magnitude and phase relation of the current in each portion of the interconnected secondary circuits, and under conditions equivalent to a line-to-ground fault. The tests were made for three different turn ratios and for several different burdens.

(*c*). Double-circuit tests, similar to the preceding single-circuit tests.

(*d*). Miscellaneous tests, such as excitation curves of the transformers, the taking of oscillograms during the tests, and the determination of the burden characteristics.

Test Equipment and Procedure

Inasmuch as a high degree of accuracy such as is required for billing metering was not deemed necessary for the intended purposes, practically all of the tests were carried out with portable voltmeters, ammeters, wattmeters, and previously standardized instrument transformers.

The primary bus currents were obtained from low-voltage loading transformers, the primary voltage of which was controlled by a 25-kva single-phase induction regulator. Although this voltage regulator was overloaded during some of the tests, involving the higher burdens, and caused some distortion of the primary voltage and current waves, there is good reason to consider, as will be shown later by the closeness of calculated values with actual test values, that the results of the tests were not affected seriously by reason of the distortion that was introduced in the primary currents of the transformers. It is believed that the very presence of distortion for the higher current values actually aided in arriving at some important conclusion as to the amount of distortion introduced in the secondary current by reason of the large third harmonic component required by the excitation component of the primary current.

All of the oscillograms shown in the accompanying figures were obtained from a cathode-ray oscillograph, having a photographic attachment. A number of check oscillograms, however, were taken with a magnetic type of oscillograph and it was found that there was a substantially close agreement of the waves obtained with the two different types of oscillographs.

Burdens

Three different types of burdens were used during the tests: (1) variable nonsaturating burdens capable of carrying secondary currents up to 80 amperes; (2) nonsaturating burdens of lesser carrying capacity for the portions of the interconnected secondary circuits in which the secondary current did not exceed 10 amperes; and (3) saturating burdens made up of relay coils, compensator coils, and other iron-core reactive devices. It was the intention at first to use actual relays for the saturating burdens, but it was found that the windings could not stand the heavy secondary currents for the period of time

Single-Phase Ratio and Phase-Angle Characteristics

Figures 1 and 2 show the ratio and phase-angle characteristics for three different turn ratios—namely 40:1, 60:1, and 80:1. There does not appear to be much necessity to enter into any detailed analysis of these curves, excepting to call attention to the fact that while in this type of current transformer there is a greater deviation from true ratio and phase angle at values of current near rated current than is permissible in instrument transformers, the reverse is true for the higher values of current. Relay performance is usually associated with current magnitudes well above the rated current of the transformer, and from this standpoint the bushing current transformer is superior to an instrument type. There are, however, cases where relays are required to operate at values of current approaching full-load current, so that the entire performance curve is of importance. The curves also bring out the fact that, particularly for relatively heavy burdens at poor power factor, the ratio and phase-angle characteristics are much better for the higher turn ratios than they are for the lower ones, and a real advantage can frequently be gained by using the higher turn ratios.

In order to show to what extent the ratio and phase-angle performance has been improved by using the extra-volume cores, it would undoubtedly be interesting to present at this point some corresponding curves for transformers having smaller volumes. Unfortunately, such data are not readily available but an equation has been derived from the test data which expresses the approximate relation between a change in volume from a reference volume and the ratio of the primary current to the secondary current. This equation, together with its derivation, is given in the appendix.

A number of tests were made on two transformers with their secondaries connected in series, curves of which are given in figure 1 and show that for burdens of less than 50 volt-amperes and with turn ratios above 40:1, there is little gain in actual accuracy, at least for the primary currents that have been considered. From the test results, and also from the equation that has been deduced for the volume-ratio relation, it appears that the ratio curves that will be obtained for two transformers with their secondaries in series for a certain burden, are approximately the same as is obtained with one transformer with half that burden.

The curves so far discussed apply to nonsaturating burdens. In figure 2, curve 3, the ratio and phase-angle curves are shown for a 200-volt-ampere saturating burden, on the basis of a five-ampere rating. During the tests, a complete record was kept of the volt-ampere burden that the saturating burdens imposed upon the secondary and it was found that a nominally rated 200-volt-ampere saturating burden actually imposed the equivalent of a 110-volt-ampere nonsaturating burden at 55 amperes secondary current. This change in the relative value of the burden will explain why the curve for a 200-volt-ampere saturating burden corresponds very closely to the curve for the 100-volt-ampere nonsaturating burden. Inasmuch as the burdens obtained in actual installations have in general saturating characteristics of widely varying degree, it may be important in some cases that these saturating characteristics be known and taken into consideration.

It is, of course, to be understood as previously stated that the test results apply only for steady-state conditions. Some information regarding the performance of current transformers under transient conditions, particularly for primary currents within the rating of the transformers, has been published.[1-3] In conducting the tests described herein, due precautions were taken to eliminate any residual magnetization of the cores which might affect the results of the tests.

Calculation of Ratio and Phase-Angle Characteristics

It is generally accepted that in the case of standard types of instrument transformers operating below the saturation point, the ratio and phase-angle characteristics can be calculated from the excitation characteristics and give results that are in substantial agreement with actual test data.

The symmetrical form of the core of the bushing transformers and the practically uniform distribution of the secondary winding, at least for the higher turn ratios, gave reason to consider that it should be possible similarly to calculate their ratio and phase-angle characteristics. This is very desirable because of the expense and equipment necessary to make actual tests, especially at the higher current values.

Figure 3 shows the in-phase and quadrature components of the excitation current as obtained in the test made on the secondary side with 40:1, 60:1, and 80:1 turn ratios. In these excitation tests, the current values were measured by dynamometer ammeters. The voltages for the lower values were measured with a combination of a high-resistance rectifier voltmeter and ratio box. This combination was checked for each reading against a dynamometer voltmeter and care was taken to insure that the check test was made under practically the same voltage wave form as in the actual test. The relative proportion of in-phase and quadrature components of the excitation current was obtained by calculation from the watt loss measurements and the volt-ampere values. The power measurements were made with wattmeters having high-resistance voltage circuits and the readings were duly corrected for the losses in the test instruments themselves, the amount of which was very considerable at the lower values of excitation current.

The procedure for calculating the ratio and phase-angle characteristics from the excitation data is well known and fairly simple. Starting with a definite value of secondary current, the voltage necessary for a specific secondary burden is calculated. For accurate results the leakage reactance of the secondary winding itself should be taken into consideration in calculating the required secondary voltage. For the transformers under consideration the combined effect of the secondary resistance and leakage reactance was approximately 0.1 ohm and is practically constant for the three turn ratios of 40:1, 60:1, and 80:1. Knowing the voltage required, the corresponding excitation components are obtained from the excitation curve and added vectorially to the secondary current and the resultant multiplied by the turn ratio to obtain the corresponding primary current. Five or six such calculations for different secondary currents are generally sufficient to obtain the ratio curve. The encircled points shown in figure 2 indicate the calculated values as obtained by this procedure. If the calculations are made by the rectangular-component method, with the induced voltage taken as the reference axis, the phase angle between the secondary current and the primary current reversed can be determined.

Inasmuch as bushing current transformers are in general provided with a number of taps on the secondary winding, in order to obtain various turn ratios, it was considered desirable to determine whether the excitation curve for a certain turn ratio would be applicable for other turn ratios. For conditions below saturation, the excitation current may be considered approximately inversely proportional to the square of the turn ratio, but for conditions in the saturation region, this relation does not hold true, and hence in using the excitation curve of a particular turn ratio for calculating the values for some other turn ratio, it is found necessary to modify the procedure for calculating the excitation components.

Designating as N_1, the turn ratio for which the excitation curves are available and as N_2 the turn ratio for which the corresponding curves are desired, the first step is to obtain the excitation values for voltage values equal to $E \times N_1/N_2$ and the second step to multiply the values so ob-

Distribution of Current in Interconnected Secondary Circuits

The determination of the distribution of current in the interconnected secondary circuit for various relaying schemes presents a more complicated problem. Tests were made for two representative circuits, one, figure 6*a*, for a single three-phase circuit with phase and ground relay burdens, and the other, figure 6*c*, for two three-phase circuits with individual phase relay burdens and totalizing phase and ground relay burdens. The tests were made simulating fault conditions resulting in current in one primary conductor only and also for faults in which there is a relatively small current in the two unfaulted conductors. The results of these tests are shown by the curves of figures 4 and 5.

In addition to providing information as to the distribution of current for the particular current transformers and burdens tested, a study of the results has been of assistance in arriving at analytical methods of calculating the distribution of current in similar circuits from the excitation characteristics of the current transformers and the impedance of the various burdens. It may be safely assumed that whatever current will flow through the idle secondaries will be in the nature of an excitation current and that no appreciable power or apparent power will be transformed to the respective primary windings of the two transformers. In other words, the impedance offered by each of these idle secondary windings is the same as the excitation impedance. In the case of primary currents in each of the three phases, a solution is obtainable by making calculations for each primary current separately, assuming no current in the other two primary conductors. The final result may then be obtained by superimposing the three separate solutions numerically or, if necessary, vectorially.

Referring to figure 6, let it be assumed that the secondary current I_A is due to a given primary current in the A conductor and that the other two primary currents are zero, the assumed condition representing a line to ground fault in which the two unfaulted line conductors carry no current.

The current I_A will be distributed in the other portions of the interconnected circuit in inverse proportion to the respective impedances of each branch. The impedance offered to the flow of any part of I_A by each of the two otherwise-idle secondary windings will depend primarily upon the voltage available at their respective terminals and their excitation characteristics. If the available voltage at the terminals of the windings can be determined, the value of the corresponding current may be obtained from the secondary excitation current and voltage relation. Therefore, in order to analyze the distribution of current in the interconnected circuit, it is necessary to determine the relative value of this voltage with respect to the current that may flow. Such a relationship may be deduced very readily for the simple circuit shown in figure 6*a*. For a more involved circuit, as for example that shown in figure 6*c*, the solution may be obtained by successive approximations. Although a rigorous solution may undoubtedly be formulated for any interconnected secondary circuit and a family of curves plotted by means of which the division of current may be determined graphically, such a solution will not usually be found to be

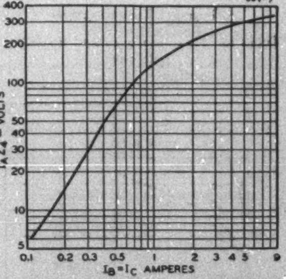

Figure 7. Curve showing current diverted from the residual circuit by each of the two idle secondary branch circuits B and C of figure 6b

$$I_A Z_4 = I_B(Z_1 + 2Z_4) + E_s$$

necessary because of the uncertainty of the accurate determination of other factors, as for example, the value of the fault current itself. It is for this reason that it is considered that certain other assumptions are justifiable.

In the treatment which follows, the assumption is made that if the power factor of all the secondary burdens be considered to be approximately 0.5, then the secondary current and the excitation current through the idle secondary windings may be added numerically instead of vectorially and thereby lead to a simplification of the problem and still give results that appear to be sufficiently accurate for the intended purposes. With the assumptions that have been mentioned, the following analysis has been made using figure 6*b*, which is the simplified circuit for figure 6*a*.

Legend

Z_t = total impedance imposed on the *A* secondary winding

I_A = secondary current in the *A* secondary winding due to primary current in phase *A*. Primary current in phases *B* and *C* equal to zero

E_1 = total voltage induced in the *A* secondary winding

E_2 = voltage available at terminals of branch circuits

E_3 = voltage available at terminals of idle secondary windings

The other symbols used below are shown in figure 6*b*.

$$Z_t=(Z_1+Z_2)+(Z_1+Z_3)Z_4/D \qquad (1)$$

$$D=Z_1+Z_3+2Z_4 \qquad (2)$$

$$E_1=I_AZ_t \qquad (3)$$

$$E_2=E_1-I_A(Z_1+Z_2)=I_A(Z_1+Z_3)Z_4/D \qquad (4)$$

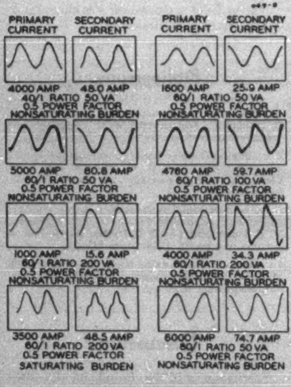

Figure 8. Oscillograms of typical primary and secondary current wave shapes

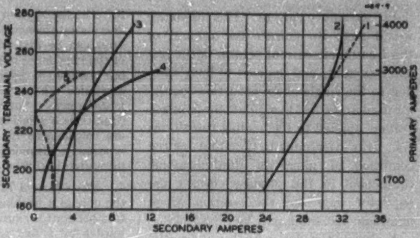
Figure 9. Relation of fundamental and third harmonic components of secondary current

200-volt-ampere nonsaturating burden, 60/1 turn ratio



Curve 1—Secondary current, equivalent sine wave

Curve 2—Secondary current, 60-cycle fundamental

Curve 3—Secondary current, third harmonic

Curve 4—Excitation current, third harmonic on secondary basis

Curve 5—Third harmonic in primary current on secondary basis

$$I_B=I_C=I_AZ_4/D \qquad (5)$$

$$I_R=I_A(Z_1+Z_3)/D \qquad (6)$$

$$E_3=E_2-I_BZ_1=I_AZ_3Z_4/D \qquad (7)$$

Substituting E_3/I_B for Z_3 in equation 7 and simplifying, gives:

$$I_B(Z_1+2Z_4)+E_3=I_AZ_4 \qquad (8)$$

Since the values I_B and E_3 are related by the excitation curve, new curves may be drawn for $I_B(Z_1+2Z_4)+E_3$ versus I_B and from such a curve the value of I_B corresponding to the value I_AZ_4 may be found.

Figure 7 shows such a curve and it is derived from the excitation curve for the 60:1 turn ratio. The burden values Z_1 and Z_4 are taken as 0.8 and 8.0 ohms respectively, the same as were the values of the burdens used in the interconnected secondary circuit in the test for which curves are shown in figure 4. A curve closely approximating curve 4 in figure 4 can be obtained by means of the curve, figure 7.

In the case of the double interconnected circuit shown in figure 6*c*, the best procedure appears to be to start with a first approximation of the current in the residual circuit and proceed to the other branches, using a voltage and current relationship as was done for the simple circuit. In connection with this particular interconnection, attention is called to the possibilities that the amount of current diverted away from the totalizing residual circuit by the A_1 branch circuit may reach values equal to or even greater than the residual current itself if the burdens of the phase relays and circuit ground relays are low compared to the totalizing ground relays.

Wave Distortion of Secondary Current

The excitation component of current introduces not only ratio errors and phase-angle displacement but also affects the secondary-current wave shape. During the tests, numerous oscillograms were taken of the primary current, the secondary current, and the secondary induced voltage. Additional oscillograms were also obtained of the excitation current. Most of those which showed considerable distortion were analyzed for the fundamental, the third, the fifth, and the seventh harmonic components. A number of these oscillograms are given in figure 8.

The theory of wave distortion by transformers in general and its effect on relay operation has been discussed in previous publications[1,4] and only a brief discussion of the test results is given here. It will be noted from the oscillograms that the distortion is very small for the low burdens. In the case of a 50-volt-ampere burden and with 60:1 turn ratio, the distortion in the secondary current does not become noticeable until the primary current reaches a value of 5,000 amperes, or 16.7 times the normal primary-current rating. In the case of the 200-volt-ampere burden, distortion begins at about 1,200 amperes, or four times the normal rating.

The curves in figure 9 which show the actual values in amperes of the fundamental and the third-harmonic component in the secondary current for different values of secondary-terminal voltages, were obtained by analyzing the oscillograms made during the tests on the 60:1 turn ratio and a 200-volt-ampere nonsaturating burden. Curve 4 in this figure was plotted from the excitation-current waves obtained during the excitation-current tests on the 60:1 turn ratio. The dashed curve number 5, shown in this figure, represents the difference between the third harmonic component actually required for excitation (on a secondary basis) and the amount of the third-harmonic component in the secondary current. This difference would seem to indicate the amount of third-harmonic current present in the primary current, and appears to have been due to the single-phase induction regulator used in the test to regulate the primary voltage applied to the loading transformers. It is interesting to note that for the condition of minimum third-harmonic component in the primary current the regulator was near the position where minimum distortion may be expected.

Analyzing the matter further, it appears tenable to state that the amount of the third-harmonic component in the secondary current is approximately equal to the vector difference of the third harmonic actually present in the primary current and the amount of third-harmonic current actually required for excitation, all values reduced to a secondary basis. Hence, the further deduction that if the fault current during a line-to-ground fault is sinusoidal, then the amount of third-harmonic component present in the secondary current should be equal to the third-harmonic component required for excitation. Although this would be true only if the burdens are nonsaturating, nevertheless, it would appear from the analysis of some of the oscillograms that with saturating burdens, the amount of the third harmonic is not altered very greatly from that with nonsaturating burdens, excepting that there is a different phase displacement of the third-harmonic component with respect to the fundamental which results in a more peaked secondary-current wave for saturating burdens than is the case for nonsaturating burdens.

As to the fifth and higher harmonics, no attempt was made to correlate the results, mainly because the analyzation of the waves for such harmonics could not be carried out within a reasonable degree of accuracy.

Conclusions

Although this series of tests was made on a specific set of bushing current transformers, an analysis of the results leads to certain conclusions which are applicable to this general type of transformer. These may be summarized as follows:

1. Bushing current transformers having cores of adequate volume and reasonably high turn ratios have characteristics which are very desirable from the standpoint of relay application and in some cases may be superior to instrument-type transformers.

2. The performance characteristics of bushing current transformers can be determined with reasonable accuracy from the in-phase and quadrature components of the excitation current.

3. The distribution of current in circuits involving interconnected transformer secondaries can be arrived at by a consideration of the impedance of the burdens in the various branches of the secondary circuit and the excitation characteristics of the current transformers. For various primary circuit conditions a solution is obtainable by making calculations for each primary current separately, assuming no current in the other primaries, and then combining results.

4. The effect of increasing the volume of the core of a bushing transformer by a certain per cent is equivalent to decreasing the burden by a like per cent. Likewise, the use of two bushing transformers in series is equivalent to reducing the burden on one to half the total burden.

Appendix

True Ratio Versus Change in Core Volume

The relation of the true ratio versus change in core volume, is a function of the excitation current required for a particular burden. If the volume is increased by changing the axial dimension and the radial dimensions remain the same, the magnetic cross section will be increased correspondingly and hence for a given number of turns in the secondary winding and for a given excitation current, the flux and the voltage induced by the flux, will be increased in the same proportion. The iron losses will of course enter into consideration but it can be shown that the effect is negligible.

For instrument transformers which generally operate below the knee of the saturation curve, factors other than the true ratio, in general, determine the core dimensions. In the case of bushing current transformers with low ampere-turn ratings, the ratio accuracy is one of the important factors which determine the core dimensions. Inasmuch as this discussion is concerned mainly with reference to conditions in the saturated region, it is of interest to analyze the relationship of the true ratio with respect to changes in the core volume, for such conditions only.

For such an analysis, the portion of the excitation curve above the knee may be represented by an equation of the form $I=k_1E/(1-k_2E)$. Now if V_1 represents a reference volume and V_2 the volume for which the ratio characteristics are desired, then if the change in volume from V_1 to V_2 is a change in the axial dimension only, the respective excitation currents, of the two volumes, will be:

For volume V_1,

$$I_{s1}=k_1E_{s1}/(1-k_2E_{s1}) \qquad (9)$$

For volume V_2,

$$I_{e1}=k_1E_{s2}V_1/(V_2-V_1k_2E_{s2}Z) \qquad (10)$$

The values E_{s1} and E_{s2} may be replaced by the respective products $I_{s1}Z$ and $I_{s2}Z$ in which I_{s1} and I_{s2} are the respective secondary currents and Z is the impedance of the secondary burden.

For the purpose of this analysis, the secondary burden is considered to have a power factor of 0.5 and on this basis the assumption is made that the excitation-current component and the secondary current are close enough in phase to permit adding their values numerically instead of vectorially. The respective true ratios for the two volumes are then given by equations 11 and 12.

$$R_1=N\left(1+\frac{k_1Z}{1-k_2ZI_{s1}}\right) \qquad (11)$$

$$R_2=N\left(1+\frac{k_1ZV_1}{V_2-V_1k_2ZI_{s2}}\right) \qquad (12)$$

Substituting $I_{p1}=R_1I_{s1}$ and $I_{p2}=R_2I_{s2}$ in the two preceding equations, and equating the two for $R_1=R_2$, gives the following relationship of the primary currents:

$$I_{p2}=I_{p1}+\frac{(V_2-V_1)}{V_1}\,\frac{R_1}{K_2Z_1} \qquad (13)$$

Hence, if the corresponding values of I_{p1} and R_1 are known for volume V_1, the corresponding primary current I_{p2}, for which the true ratio is equal to R_1, may be calculated. The value of the constant k_2 may be determined from the excitation-current curve.

The conclusion that may be deduced from curves plotted by means of equation 13 may be stated in various ways but it would seem that the following would best serve the purpose, namely, that the gain in ratio accuracy that is obtained by increasing the axial dimension of the core by a certain percentage is approximately the same as would be obtained with the original volume by reducing the value of the burden the same percentage.

Ratio Versus Burden Impedance

For approximate determination of the ratio curve for a burden of Z_2 ohms impedance, if the curve is known for a burden of Z_1 ohms and of the same power factor as Z_2, the following equation has been found to give sufficiently accurate results for conditions in the saturating region.

$$I_{p2}=I_{p1}+\left(\frac{Z_1-Z_2}{Z_2}\right)\frac{R_1}{KZ_1}$$

The value of the constant k is the same as in the preceding equation 13.

A Proposed Method for the Determination of Current-Transformer Errors

G. CAMILLI
MEMBER AIEE

R. L. TEN BROECK
ASSOCIATE AIEE

CURRENT TRANSFORMERS for relay service must be able to function with reasonable accuracy under very high overload conditions, and it is therefore necessary that their accuracy for such high currents be verified. However, in performing the usual accuracy test at very high currents, certain difficulties are encountered—the principal ones being:

(*a*). The difficulty of providing large amounts of power at large current values and bus-bar type wiring required. The kilovolt-amperes required at 20 times normal current is 400 times that at normal current.

(*b*). The necessity for standard burdens capable of withstanding heavy currents.

(*c*). The necessity for taking the meter readings very rapidly—within a few seconds—in order to avoid overheating of the current-transformer windings.

This paper proposes an indirect method for determining the accuracy characteristics—phase angle and ratio—of a current transformer for both normal and abnormal currents, whereby the difficulties of test mentioned above are obviated, with no sacrifice of essential accuracy. It consists in the determination by test of the impedance and of the excitation characteristics of the transformer and calculating from them the ratio and phase-angle errors of the transformer.

In this respect the proposed indirect method, as a method of calculation of the *current* regulation of the transformer, falls in identically the same category as the standard procedure for determining the voltage regulation of a power transformer indirectly from impedance measurements.

Equivalent Circuit of a Transformer as Reduced to 1:1 Ratio

The errors of a current transformer arise from the fact that not all of the primary current is transformed, a component (I_e) being used to excite the core. This may be seen more clearly by referring to the conventional equivalent circuit of a transformer as shown in figure 1. In this diagram *R* and *X* are respectively the resistance and the reactance of the external burden, and r_1, r_2, x_1, x_2, respectively the resistances and reactances of the primary and secondary windings.

The exciting current is conceived of as occasioned by a load in a fictitious third winding. From the equivalent circuit it is easily seen that the value of the by-passed exciting I_e depends upon the value of the induced voltage E_2, and it follows therefore that the characteristics of a current transformer are defined when the values of r_1, r_2, x_1, and x_2 are known and the exciting current I_e is given as a function of E_2.

For if these values are known, then it follows from the equivalent circuit that:

$$I_2 = I_1 - I_e \tag{1}$$

and:

$$E_2 = I_2\{(r_2+R)+j(x_2+X)\} \tag{2}$$

and consequently the ratio $|I_2|/|I_1|$ and the phase angle ($\angle I_2 - \angle I_1$) can be determined as illustrated below.

Determination of the Leakage Reactances

Of course r_1 and r_2 can be measured directly across each winding. In order to be able to measure the primary and secondary leakage reactance voltages directly it is necessary that there be only load currents in the windings and no exciting current—that is, the primary and secondary ampere turns must be exactly equal and opposite. This condition can be realized in a 1:1 ratio transformer by connecting the primary and the secondary windings in series opposition and forcing the desired current through them.[1] The voltages measured across each winding are then caused respectively by the "primary" and "secondary" internal impedances of the transformer. Knowing the current, the leakage reactances x_1 and x_2 can be calculated.

To insure equality of primary and secondary ampere turns in transformers other than 1:1 ratio, some expedient must be introduced. One such method is illustrated in figure 2. This figure shows a bushing-type current transformer. However, the scheme can be used for any current transformers provided they do not incorporate methods of compensation other than the regular turn compensation. In figure 2, *B* is the transformer of which it is desired to determine the secondary leakage reactance; *A* is an auxiliary current transformer which is used to balance the primary and the secondary ampere turns of the transformer *B*.

The auxiliary "balancing" current transformer *A* is wound with suitable taps and its ratio of transformation is chosen to be *identical* with that of current transformer *B* under test. The auxiliary current transformer *A* has also an exploring winding *N*4 which is connected to a vibration galvanometer.

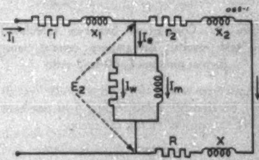

Figure 1. Equivalent circuit of a current transformer

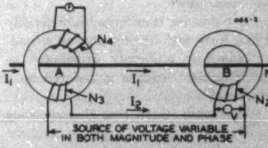

Figure 2. Method for determining the secondary impedance of a current transformer

The primary winding of the transformer to be tested is connected in series with the primary winding of the balancing transformer and to a source of voltage supplying the primary current. Likewise the secondary windings of the transformers are connected in series and to a source of voltage supplied by a phase shifter.

The phase and magnitude of the current supplied by the phase shifter are ad-

justed until the flux in the balancing transformer is zero. This is determined by a zero reading on the vibration galvanometer. The value of I_2 is measured by an ammeter and the voltage V by a voltmeter, across the secondary of the transformer B. The latter is proportional to the internal secondary impedance of the transformer.

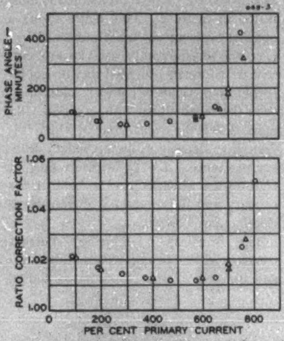

Figure 3. Comparison between calculated and test results, 300-ampere current transformer number 1, 60-to-1 ratio

Bushing type with distributed secondary winding; burden 50 volt-amperes, 100 per cent power factor, 60 cycles

⊙—Calculated △—Test

The balancing transformer is preferably of ring form with its primary and secondary windings uniformly distributed so that magnetic leakage is reduced to a minimum.

It has been stated that the balancing transformer of figure 2 needs to be of the same ratio as the current transformer under test. To fulfill this requirement it is necessary to know the secondary number of turns of the current transformer. There are several ways in which this can be obtained by test,[2] but the description of these methods falls outside the scope of this paper. Of course the simplest way is to obtain this information directly from the manufacturer.

In these tests, two methods were used for obtaining the variable source of voltage:

(*a*). By deriving this voltage from a conventional phase shifter (a wound-rotor polyphase induction motor will serve)

(*b*). By the use of two generators the shafts of which are connected mechanically. The stator of one of the generators can be turned with respect to the other

The voltmeter V needs to be of very high resistance. A good plan is to use a copper-oxide voltmeter having an internal resistance of about 1,000 ohms per volt. The Tinsley-Gall a-c potentiometer can also be used to read the above voltage.

Variations of Secondary Reactance With Secondary Current of the Current Transformer

Theoretically the division of the leakage reactance of a transformer varies with the secondary current. The reason for this is that changes in permeability of the core at various densities affect differently the reluctances of the external and internal parts of the magnetic circuit—neither the iron magnetic circuit nor the air magnetic circuit, which are in parallel, having uniform section or length. It is found, however, by actual test that these changes are quite limited and not large enough to affect considerably the accuracy which can be obtained by the proposed method of test. Actual test results of the secondary reactance at two or more values of the secondary current are tabulated under the item of "Test Results".

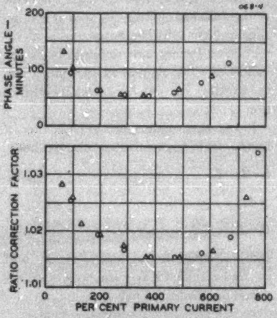

Figure 4. Comparison between calculated and test results, 300-ampere current transformer number 2, 60-to-1 ratio

Bushing type with secondary winding concentrated on approximately one-fourth of the circumference of the core; burden 50 volt-amperes, 100 per cent power factor, 60 cycles

⊙—Calculated △—Test

Determination of Magnetic Properties of Core Material

In order to determine the performance of a given transformer under definite conditions of load, it is now necessary to obtain values of the watt and wattless components of the exciting current (I_e) corresponding to the voltage E_2 which is applied across the secondary terminals of the transformer. It should be noted from the equivalent circuit of figure 1 that theoretically to obtain the actual value of I_e corresponding to the induced voltage E_2 there should be applied across the terminals of the transformer a somewhat higher voltage; but in general the voltage drop caused by the current I_e flowing through the internal impedance of the transformer is very small and can be neglected.

In the measurements of watts and exciting current, the fundamental components of these quantities must be taken. In the tests made for the preparation of this paper, a Tinsley-Gall a-c co-ordinate potentiometer was used.[3] Other methods can be used when this equipment is not available. For instance, the fundamental component of the exciting current can be obtained by means of a separately excited wattmeter, the separate excitation furnished by a phase shifter.

Calculation of Current-Transformer Characteristics From Test Results

If the magnetic properties of the core of the current transformer and the leakage reactance of the secondary winding are known, the ratio and phase angle for any secondary current or burden on the current transformer can be calculated quite accurately.

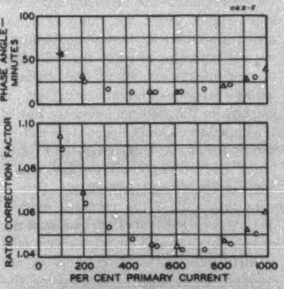

Figure 5. Comparison between calculated and test results, 200-ampere current transformer number 3, 40-to-1 ratio

Bushing type with secondary winding concentrated on approximately one-sixth of the circumference of the core; burden 50 volt-amperes, 100 per cent power factor, 60 cycles

⊙—Calculated △—Test

Agnew[4] gives the following simplified formulas for calculating the errors in current transformers:

$$\text{ratio } (R) = \left(n + \frac{M \sin \phi + F \cos \phi}{I_2}\right) \frac{1}{\cos \theta} \quad (3)$$

$$\tan \theta = \frac{M \cos \phi - F \sin \phi}{n I_2} \quad (4)$$

where:

I_2 is the secondary current
n is the ratio of number of secondary to primary turns
θ is the phase angle of the current transformer
ϕ is the phase angle of the secondary current with respect to the induced voltage
M is the magnetizing component of the core exciting current
F is the corresponding loss component of exciting current (due to hysteresis and eddy losses in the core)

In order to obtain M and F it is simply necessary to multiply the wattless volt-amperes (VA) and the watts (W) respectively by:

$$\frac{n}{E_s}$$

After obtaining the internal secondary impedance of the given transformer and its excitation characteristics by the use of formulas 3 and 4 it is relatively a simple matter to determine the ratio and phase angle under any conditions of current and of burden. The method will be illustrated by an example and the results compared with test results obtained by a conventional method of testing.

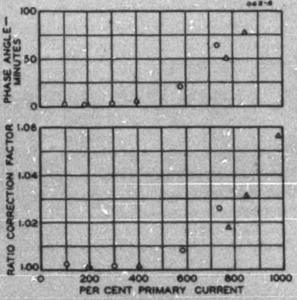

Figure 6. Comparison between calculated and test results, 100-ampere current transformer number 4, 20-to-1 ratio for 4,500-volt circuit

Wound-type current transformer; burden 50 volt-amperes, 50 per cent power factor, 60 cycles

⊙—Calculated △—Test

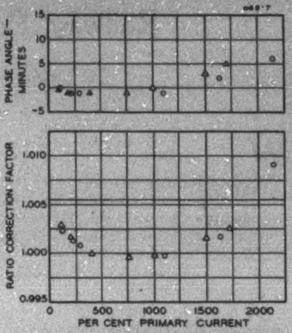

Figure 7. Comparison between calculated and test results, 50-ampere current transformer number 5, 10-to-1 ratio for 69,000-volt circuit

Wound-type current transformer; burden 50 volt-amperes, 50 per cent power factor, 60 cycles

⊙—Calculated △—Test

Sample Calculation

To illustrate the method of test and the necessary calculations to determine the current-transformer errors, the following example is given:

Characteristics required on a bushing-type current transformer rated 300/5 amperes, having a concentrated secondary winding. Core dimensions—inside diameter = 8 inches, outside diameter = 10 inches, height = 3 inches
Secondary turns = 60

External burden = 50 volt-amperes at 100 per cent power factor

Balancing transformer consisting of a bushing current transformer having a core of the following dimensions: inside diameter = 16 inches, outside diameter = 20 inches, height = 3 inches. Secondary turns = 60 uniformily distributed over the core. Exploring winding of 100 turns—also uniformily distributed.

(a). DETERMINATION OF SECONDARY REACTANCE

Test made at five amperes, 60 cycles
Voltage read across the secondary of the current transformer under test (at balance) = 1.70 volts
Measured secondary resistance of the transformer = 0.14 ohm
Calculated secondary reactance of the transformer = 0.31 ohm

(b). TEST ON THE MAGNETIC CHARACTERISTICS OF THE CORE

For the sake of brevity only a few points are given:

E	W	I_e	F	M
60.12	20.64	0.775	20.58	41.70
70.32	29.62	1.31	25.50	74.4

(c). CALCULATION OF THE CHARACTERISTICS OF THE CURRENT TRANSFORMER

External burden—50 volt-amperes at 100 per cent power factor
$R = 2$ $X = 0$
Internal burden—$r_2 = 0.14$, $x_2 = 0.31$
Total secondary impedance:

$R + r_2 = 2.143$
$X + x_2 = 0.31$
$Z = 2.16$

$$\cos \phi = \frac{2.14}{2.16} = 0.99$$

$$\sin \phi = \frac{0.31}{2.16} = 0.143$$

E	I_2	M sin ϕ	M cos ϕ	F cos ϕ	F sin ϕ	R	θ
60.12	27.8	5.98	41.3	20.4	2.94	60.96	78′
70.32	32.56	10.68	70.36	25.26	3.66	61.14	2°, 1′

Table I. Measured Secondary Impedances

Transformer Number	r_2	X_2	At I_2 (Amp.)	Remarks
1	0.132	0.002	5	
2	0.143	0.31	5	
3	0.083	0.274	2.3	
3	0.085	0.276	4.55	
3	0.084	0.274	7.83	
4	0.29	0.249	2	
5	0.52	3.65 3.48 3.30 3.19	2.68 4.79 7.3 8.7	Transformer compensated (Wilson method)
5	0.52	2.79 2.79 2.76	2.67 5.25 9.40	Tranaformer uncompensated

These results are compared with conventional test in figure 4.

Test Results and Discussion

The following transformers were tested:

1. Figure 3—bushing-type current transformer, wound core, secondary winding uniformly distributed. Ratio 300/5. Inside diameter of core = 8 inches
2. Figure 4—bushing-type current transformer, wound core, concentrated secondary winding—otherwise same as above
3. Figure 5—bushing-type current transformer, wound core, concentrated secondary winding. Inside diameter of core = 18 inches. Ratio 200/5
4. Figure 6—wound-type current transformer for 4,500-volt circuit. Ratio 100/5
5. Figure 7—wound-type current transformer for 69,000-volt circuit. Ratio 50/5. This transformer can be compensated according to the Wilson method. Tests were made with and without compensation

From table I it is noted that the secondary reactance of an annular core with distributed secondary winding is negligible, which confirms the findings of other investigators.[5] Table I and figures 3 to 7 also show that from a practical standpoint the secondary reactance is constant and a measured value at normal current can be used for overcurrent calculations, provided the transformer does not incorporate any compensating scheme other than simple turn compensation. With certain compensating schemes an estimation of this reactance can be obtained by testing at several points and extrapolating. This value can be used when errors are small.

The curves in figures 3, 4, 5, 6, and 7 show good agreement between test values and calculated values up to saturation of the core. The results obtained above saturation in either method (test or calculation) are somewhat indefinite. The method used for the testing recognizes only fundamental values of the primary and secondary currents. At these points above saturation, distortion is unavoidable. It is difficult to duplicate this distortion by calculation, and furthermore there is some doubt whether results in this region are of much value since some relays respond to fundamental values, some to effective values, some to peak values, and others to intermediate values. It should be pointed out, however, that overcurrent tests are more often used to compare the performance of two or more different current transformers and for such purposes the proposed method of indirect testing would appear satisfactory.

Conclusion

A method of testing current transformers has been described which eliminates a number of serious difficulties encountered in the usual methods of testing and is applicable with satisfactory accuracy under practically all current and burden conditions.

Discussion

Discussion will be found in the 1940 annual Transactions volume and in the 1940 "Transactions Supplement" to Electrical Engineering.

Railway Power Supply

PHILIP TORCHIO
FELLOW AIEE

While all industries depend on the use of power few are more vitally affected by the circumstances of its use than the transportation industry. In this industry power not only represents a large item in the total cost of operation but, by the varied forms and ways in which it can be applied, exercises an important influence in the creation of conditions favorable to more efficient movement of freight and passengers, improvement in the standards of service and resultant promotion of the business.

The determination of the type of power most advantageous in a specific case presents a multiplicity of problems which require detailed study by persons who possess extensive practical experience. In a general way, however, all engineers recognize the fact that, where electric power must be utilized in small quantities in widely separated locations, it is more economical to install the generating plant at the point of use. As these locations become more numerous and are grouped together, better results can be secured by generating the power centrally and distributing it to the individual users. Similarly, in generating power for the movement of trains, where they are limited in number and size the conventional method of using a steam locomotive or other power unit on each train is followed with satisfactory results. As the trains increase in number and size a point is reached where it becomes far more economical and satisfactory from every standpoint to install the power-generating facilities at a central location and supply the current to motors on the trains through a distribution system.

In any specific case the railroad executive will have to co-ordinate and evaluate all the gains possible from electrification but, in general, past experience has shown that it may be considered as a means of moving trains in dense-traffic territory at no additional cost and in many cases at considerable saving, while at the same time providing the public with faster schedules and more reliable service and the management with increased capacity of plant. The full benefits of a railroad electrification usually are not secured until after it has been in service for a sufficient length of time to enable the management, through education, training, and supervision, to take full advantage of the improved tool with which it is supplied.

As further experience is secured with railroad electrification the first cost and operating expenses should be materially reduced by using the same intensive methods of supervision and development which, in the past, have produced so much improvement in the service and reduction in the cost of steam operation. As these results are obtained, electrification will doubtless extend to portions of railroads which, under present conditions, are not considered to be suitable projects for this method of handling transportation; the intensified study which many power companies are giving to the subject of railway supply will help to make these results possible.

Paper 40-4, recommended by the AIEE committee on transportation, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 1, 1939; made available for preprinting November 22, 1939; released for final publication March 21, 1940.

Philip Torchio is retired vice-president, Consolidated Edison Company of New York, Inc., New York, N. Y.

Changing Aspects of Power Supply

When electricity first became available for traction, it found a ready field of application in the transportation of passengers in cities and towns and a new industry was soon developed in which it was used exclusively for motive power on account of its remarkable flexibility in handling such traffic. In the case of existing transportation systems, however, the substitution of electricity for steam encountered the serious obstacle that it would require large new investments, involving the addition of wayside structures, equipment and conductors, possible changes in track and facility provisions, and a complete change in locomotive equipment. For this reason the railroads found it more advantageous to continue their long-established policy of improving the economy of steam locomotives, designing different types for specific services and, more recently, of adopting internal-combustion engines for high-speed light passenger trains, for yard switching, etc. Nevertheless, in certain situations other weighty considerations made it desirable or necessary to adopt electric traction. This was the case in the early electrifications of important terminals serving considerable suburban passenger traffic and, later, where heavy freight traffic and steep grades, or the carrying of freight and passenger traffic in competition with other means of transportation, made the change to electric traction profitable.

In the foregoing developments, the role of the utilities in connection with the supply of power for traction, has passed through two different phases:

Many years ago, when electric traction was first introduced for urban rapid transit and, subsequently, for the more important steam-railroad terminals, the electric utilities were not sufficiently developed to supply advantageously throughout their territories, the large quantities of special current required for traction. Consequently the transportation companies, as a rule, installed their own plants and extensive distributing systems.

Later, because of their rapid growth, the utilities had greatly expanded their generating and distributing facilities and found themselves in a position to supply power to the transportation companies more advantageously than the latter could produce it. This change in conditions prompted the consummation of many contracts for the supply of power.

Type and Scope of Contracts

We shall subdivide these contracts into two types:

First—Those covering the supply of power to railways operating their own generating and distributing plants.

Second—Those covering power sales to railways to be electrified without power plants of their own.

A utility, in dealing with these two classes of contracts, is confronted with distinctly different problems. In the first case it has to prove to the prospective customer that its service will be more advantageous than can be obtained from his old plant even if it is improved by an economical modernization. In the second case the utility has to prove that its service will be more advantageous than the customer can obtain from a heavy investment in modern generating and distributing plant to provide the requirements of the road to be electrified.

First Case

Where the railways owned good-sized 25-cycle plants for generating their power requirements, and the utilities had considerable 25-cycle capacity installed for their own use, the parties were able to evolve special workable power arrangements based on interconnecting the railways' plants with the utilities. The less efficient railway plants were then operated for a minimum number of hours as in the case of the utilities' own generating capacity of older vintage, thereby realizing material operating savings which were equitably shared by both parties. In addition, the railways were relieved of the necessity of generating power, which must be a side issue for them since they are basically engaged in providing transportation, rather than in producing and distributing power economically.

These special power arrangements were dictated by the desirability of making full use of the unexpired economic life of the railways' plants without the necessity of large expenditures for their modernization, as is being successfully done on the utility systems, with assured increasing loads, by the installation of topping turbines. The railways are handicapped in carrying out a modernization program because it is generally difficult for them to dispense with a substantial part of their generating facilities during the protracted period required for reconstruction, and, if the construction plans are so worked out that the existing equipment is not disturbed the cost of the new facilities is likely to be excessive. Furthermore, since their rebuilt plants, in some cases, must be operated at the relatively poor traction load factor, they are not in a position to make the best use of the modern equipment and the operating savings may not be sufficient to counterbalance the added fixed charges. The utilities, by contrast, are in a position to modernize plants and to operate them advantageously for base-load generation, using the railway plants for emergency or standby service thereby filling the former role of the modernized plants. The old railway plants then readily fit in as a part of a co-ordinated program.

There is no standard form for such arrangements because the details to be covered vary greatly in each situation. Special provisions of the contracts usually are similar to those for straight power sales contracts hereafter described. The only essential requisite is that the net results must be such that the railways obtain the service at a lower cost than they could secure for themselves by modernizing their plants in order to raise their efficiencies to the standard afforded by the advancement in the art; and that the utilities obtain sufficient revenue to cover all operating expenses and fixed charges, including amortization of any new investment, plus allocated general expenses, taxes, and a fair share of the savings derived from the bulk production of the increased output. These savings will ultimately accrue to the benefit of the general customers in reduced rates.

Second Case

Contracts for the sale of power to traction companies not owning power plants are not essentially different from the usual form of "demand and energy rate" contracts and include such items as:

term of the contract—character of energy—points of delivery—use to be made of the energy—price of "demand" and "energy" charges—price adjustment for changes in cost of fuel, when power is produced by steam—definition of billing demands—service connections—billings and payments—etc.

In addition such important contracts also contain appropriate provisions, including:

dates for beginning specified partial services and full service—clauses to insure diligence in providing regular and uninterrupted service—access to records—testing of measuring instruments—arbitration—reduction of rates if more favorable rates are given other customers under substantially similar conditions.

In the preparation of each contract, the various provisions are carefully drafted to conform to the unique requirements of the case. Certain distinguishing characteristics of railway contracts, and the considerations on which they are based, are as follows:

(*a*). **A relatively long period of time is specified for the term of the contract and its renewals, if any.**—These contracts being for large amounts of important service, it is obvious that the parties must have a relatively long period of guaranteed operation of the facilities provided for the service. Contracts are rarely written for less than 10 years and usually cover longer periods of operation up to 20 years with provision for extension of time should the utility make substantial additions to its facilities for the railway's use during the initial period.

(*b*). **A guarantee of payment for a minimum amount of service each year is usually included.**—The utility must have a guaranteed minimum payment in order to cover the overhead charges and provide, during the term of the contract, for reasonable amortization of the special investment made.

(*c*). **Unusual methods of determining the monthly maximum demand for billing are used.**—The operation of a railroad is subject to occasional large variations of maximum demand from causes extraneous to the normal operation. These fortuitous conditions should not be allowed to penalize the railroad unduly. Hence the average of the three highest clock-hour maximum demands in each month has been adopted in a number of contracts as the billing demand. Furthermore, in cases of emergency, the large drafts of power following accidents or abnormal and unforeseen increases in traffic for short periods of time are usually furnished by the utilities, if they have the capacity available, without increasing the billing demand.

(*d*). **A provision is included which requires that each monthly billing demand shall not be less than a specified percentage of any previous billing demand.**—This supplements the requirements of (*a*) and (*b*) and takes into account the special characteristics of the railway's fluctuation in business from year to year. Except for some of the urban lines this fluctuation is very large, and if the railways were to pay for a high percentage of any previous demand when the traffic has shrunk considerably, their income would be diminished when vitally needed. For this reason they prefer that the unit demand charge be figured high enough to compensate the utility fully during the term of the contract, and that the guaranteed percentage of any previous billing demand which determines the yearly payment for "demand charge", be made more proportional to the amount of maximum load taken during each year.

(*e*). **The practice as to whether the railway or the utility should furnish and operate the machines required to deliver direct or single-phase current is not uniform.**—In the case of railroads electrified during the last few years the tendency has been to have the utility furnish, house, and operate such apparatus and supply energy directly to the trolley or transmission lines. In such cases provisions are made in the contract price for a proper compensation to cover the operating costs, conversion losses, and fixed charges including amortization. Clauses are also included for transferring ownership to the railway in the event of termination of the contract, at a sale price proportionate to the unamortized investment.

(*f*). **The utility, in establishing these differences in the terms of various contracts, carefully analyzes the effect of each variation and accordingly provides price differentials which will avoid discrimination among customers.** The general clause on reduction of rate if more favorable rates are given other customers also protects each purchaser in respect to these special provisions.

Underlying Economic Factors

The utilities are justified in making the foregoing departures from their standard forms of power contracts in the case of electrified railways, since experience has shown that this valuable business could not be secured without giving the underlying economic factors full consideration from the standpoints of both the railways and the utilities. We have already made occasional references to these factors but it is also important to explain more comprehensively how they affect the two industries.

LOAD FACTOR

In general the utilities have a much higher use of their maximum demand than the railways which means that they are able to render more service per kilowatt of plant capacity. This is caused by the great variety of their customers and the resulting time diversity of maximum demand and use of the service. Furthermore, although the railway's load factor is, in general, less favorable than the utility's, when the two loads are superimposed with their diversity in time of respective maximum demand, the combined load factor is improved and conditions are created for realizing substantial economies in plant investment. These investment economies are, of course, further enhanced by a saving in the amount of spare capacity which would be required if the railway were to install and operate an independent generating system for the lines to be electrified. Similar economies may also be realized in connection with the power transmission system. Therefore, if the railway electrification loads are supplied by a heavily-interconnected utility industry these factors will produce economic results to the advantage of both the railways and the utilities.

RATE OF GROWTH

The utilities with their continuous growth in load, in contrast with the more or less stationary load of a railroad for a given situation, are in a better position to continue to improve their operating economies, as they have done in the past.

These economies were realized in part from the fact that the quantities of power handled by the electric utilities became so large that it was possible for them to install generating and transmission units of large capacity with correspondingly lowered unit costs, reduced operating labor costs, and improved efficiencies. At the same time, the utilities were enabled to produce the major portion of their power requirements from their newer and more efficient units, by operating them at high load factors and gradually relegating their older plant to usage for peak or standby service.

For illustration, the graph, figure 1, gives the distribution of capacity and output according to the date of installation of units for a large system during the year 1934. It shows that of the total capacity, the 20 per cent installed before 1919 was used to give less than 2 per cent of the total output and the 50 per cent installed before 1926 was used to give less than 28 per cent of the total output while the other 50 per cent installed between 1926 and 1934 and incorporating the latest advancements in the art as to the size and efficiency of machines, higher steam pressure, higher steam temperature, more efficient boilers,

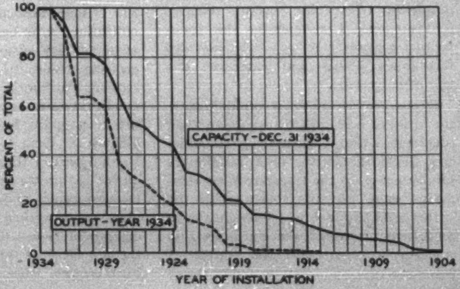

Figure 1. Total generating capacity installed in or prior to indicated year compared with energy generated by corresponding units during the year 1934

and all other station improvements generated 72 per cent of the total output. This progress in securing higher economies is a continuous one as long as the industry is growing.

SOURCES OF POWER

In contrast with the foregoing favorable situation of the utilities in supplying power, it is evident that large-scale electrifications under present-day conditions, if served with power by the railways themselves would either require several suitably located and relatively small power plants, which necessarily would involve high unit investment and operating costs, or alternatively would require excessive investment in transmission facilities in order to distribute over a widespread area from some centrally located plant. In either case a relatively high amount of reserve capacity would be needed to insure the reliability of the service. The advantageous position of the electric utilities with their large and economical plants at many load centers, and large-capacity transmission facilities generally available at other load centers not directly served by generating plants, is obvious.

Status of Electrification

Notwithstanding the fact that steam railroads have had the possibility of using electric traction available to them for many years, they have not found it feasible to utilize this form of power except for the few special cases to which we have referred. The reason for this has been stated to be the large new investment which would be required. It would be appropriate to add practical illustrations of the net results of operation before and after electrification, taking account of the changes in capital investments and all other factors affecting the net results. Unfortunately most of the comparisons available to the public deal in generalities or apply only to a specific phase of the subject. Furthermore, any comparison would be entirely dependent on the circumstances of the case, and would vary widely between different roads, or divisions of the same road, depending on traffic, profile, speed, and many other conditions.

Comprehensive data on the results of electrification have been published for the Chicago, Milwaukee, and St. Paul Railroad, and a recent analytical study of all the factors affecting the total net results of the Italian Railways may be found in Mr. Carli's report to the 1938 World Power Conference on "Comparative Results of Operations of Italian Steam and Electric Railways for the Year 1936–37" (*Elettrotecnica*, April 25, 1939). From the latter we can draw the conclusion that, apart from other important advantages *unrelated to the operating costs*, their savings by the use of electric traction are mainly due to the high cost of coal in Italy and would disappear entirely if their cost of coal were the same as in the United States. These conclusions are arrived at by a comparative analysis of Mr. Carli's tabulation, for the steam and electric systems, of all expense items that relate to the supply of power and operation of the transportation department, including interest charges on investment in locomotives and power equipment.

The aggregate expense per ton mile of steam traction was 17 per cent higher than for electric traction. Unfortunately Mr. Carli's study compares steam traction with electric under great differences in density of traffic; the electric lines with only one-third the mileage of the steam lines, carried $17^1/_2$ billion ton miles against $21^1/_2$ billion ton miles carried by the steam lines. This fact greatly favors the electric-traction system, and seriously limits the absolute value of the comparisons, although the relative value of the conclusions reached above are not disturbed. In analyzing the items of expense we find that the cost of coal was of the order of $8.70 per short ton. The equivalent cost for the class I railroads in this country was about $2.43, this low average price being partly due to the Interstate Commerce Commission accounting system which excludes from fuel expenses any cost or charges for its transportation on the reporting company's lines. But even if a liberal allowance were made for such charges, the American price per ton of fuel would have been less than one-half that of the Italian Railways. If the price in Italy had been on the same relative basis as in America the excess cost of steam traction would have been eliminated entirely.

The electric lines handled the 17.5 billion ton miles with an average consumption of 43 watt-hours per ton mile or a total of 750 million kilowatt-hours. Of this total the railways generated about one-fourth in four hydroelectric stations owned by the State, and purchased three-fourths from the utilities at 42 high-voltage delivery points. These results give a practical confirmation of the conclusions reached under the heading of "Underlying Economic Factors" and emphasize the fact that such economies are secured jointly with an infinitely greater insurance of continuity of service which is provided, not only by the large number of high-voltage delivery points, but also by the numerous generating plants back of them, which insure the supply of the utilities under abnormal conditions of operation.

Future Possibilities

Up to 1937 the railways in the United States had only electrified to the extent of consuming 1,627 million kilowatt-hours, which is estimated to be less than $2^1/_2$ per cent of the total business. This would indicate that, under present conditions and prevailing prices of coal, electricity has not demonstrated definite advantages over steam traction except in a very few special cases where other considerations unrelated to operating costs might have influenced the change or where heavy traffic conditions and relatively high operating speeds prevail. We need considerably more analytical information to clarify the problem as to why the largest industry in this country has not adopted electric traction more widely. For the present, therefore, it is impossible to make any sound forecast of its probable growth. We must, however, bear in mind that changes in this country are apt to be rapid and powerful and that the utilities may eventually find in the railways a field for steadily expanding their power sales. The theoretical demand for such services, if all the railways were to be electrified would be of the order of three-fourths the present output of the entire central-station industry in the country. Only a third of this potential total would be as large as the present consumption of all residential consumers.

There are many obstacles in the way of further electrification which are not related to the cost of electric power but, to the extent that this cost influences the whole problem, the utilities have demonstrated that the railways can buy electricity from them more advantageously than they can secure it in an alternative way. In securing this business the utilities would be benefiting all their customers, because the economies realized from service to the railways ultimately accrue to the advantage of all users of electricity.

Discussion

Discussion will be found in the 1940 annual TRANSACTIONS volume and in the 1940 "Transactions Supplement" to ELECTRICAL ENGINEERING.

Overcurrent Performance of Bushing-Type Current Transformers

C. A. WOODS, JR.
ASSOCIATE AIEE

S. A. BOTTONARI
ASSOCIATE AIEE

Synopsis: Conventional methods used for defining and comparing current-transformer performances are commonly based on their ratio and phase-angle characteristics. For years, these characteristics have been continuously improved, particularly with respect to the requirements for metering service. However, from the standpoint of circuit protection, current-transformer application becomes more involved and as a result, increased attention has been given it.

A better knowledge of transformer performance is necessitated by the requirements of new relays and protective schemes. Attention to the influence of the d-c component in short-circuit transients is especially necessary when using high-speed relays. Also, in differential connections, the necessity for equivalent matching of saturation characteristics is essential. These are illustrations of the types of problems which ratio and phase-angle characteristics alone do not solve. The analysis of open-circuit saturation curves has proved of immense value in the solution of these problems.

This paper gives results of investigations on bushing-type transformers that indicate the proper choice of analysis procedure and the limitations of the various methods for determining performance under overcurrent operating conditions.

THE PURPOSE of this paper is to present the results of an investigation on the scope and limitations of saturation and loss curves in the application of bushing current transformers to relaying problems involving the overcurrent performance. The investigation covered the method of taking such data, the methods of calculation and the accuracy of ratio and phase-angle performance as calculated from it, and the application of the data to simplification of relaying problems.

The use of voltage-saturation and watt-loss data to analyze the performance of magnetic circuits has always afforded a means of predetermining the performance of devices associated with such circuits. Generators, transformers, and similar devices have their basis of design on these known characteristics of the magnetic material used. This leads to simplicity of investigation for a given set of conditions, and provides information which otherwise could be obtained only with the conditions peculiar to the investigation.

Within certain limitations it should be possible to formulate a practical analysis of the overcurrent performance of bushing-type current transformers in terms of the induced voltage and associated losses in a specified magnetic circuit independent of the operating conditions. The latter would be specified in terms of ratio, secondary burden, and primary-current range. These characteristics, if given in a desirable form, should be as suitable to the application engineer as they have been to the design engineer, and should find a wide range of usefulness.

Transformer Performance Characteristics

The conventional method for defining and comparing the performance of current transformers has been their ratio and phase-angle characteristics. Considerable information has been published relative to the improvement of these characteristics, particularly over the ranges of load currents and burdens encountered in metering service. These characteristics, particularly ratio, have been extended to cover the higher ranges encountered in relaying service.

With the advent of new relays and protective schemes the application of current transformers has become more involved, and the use of the conventional performance data has often proved inadequate for successful solution of certain types of these problems. Recently much progress has been made in application of high-speed relays[2,3] with the attending problem of transient performance by the use of open-circuit saturation curves. Many have found this criterion of great benefit in the solution of problems involving the overcurrent performance of bushing-type current transformers.

Saturation and Loss Data and Vector Diagram

A theoretical consideration of the vector diagram of the current transformer figure 1, which is the same as that for the conventional voltage transformer, shows that in general the primary constants of resistance and leakage reactance do not influence the performance, except by virtue of the indirect influence of the primary upon the secondary leakage reactance.[1] The difficulty of separating these leakage reactances is well known, and any effective use of the open-circuit saturation curve for calculating performance requires a knowledge of the approximate value of this reactance. For through-type current transformers with a ring-type core, symmetrically spaced, distributed secondary winding, and reasonably spaced primary conductor, the secondary leakage for low and medium core densities is sufficiently small that it can be neglected.[1,4] The usual bushing-type current transformer fits these requirements and hence the open-circuit saturation curve and equivalent circuit should lend themselves to the simplification of many problems involving the knowledge of its performance.

Method of Measuring Excitation Characteristics

Of the numerous methods of obtaining saturation and loss data on current transformers, the direct measurement of these quantities on the secondary winding with the primary open-circuited has been chosen for its simplicity, flexibility, and economy. It has been found when making such measurements that the wave shapes of the currents and voltages, and the types of measuring instruments used have a direct bearing on the results. Previous experience indicated satisfactory calculations of transformer performance could be made from saturation and loss data taken by impressing sine wave voltages and measuring the rms voltages and currents.

As it is often difficult to determine and maintain wave form when obtaining saturation and loss data, tests were made to determine the influence of wave shape. A 600/5 multiratio bushing current transformer for a 138-kv oil circuit breaker was tested; first, using sine-wave impressed voltage, and second, circulating sine-wave exciting current. As illustrated by figure 2, both voltage and current are essentially sine wave for core densities below saturation, while either one or the other, or both, must be distorted when the core becomes saturated. The results obtained throughout the complete range of core densities are shown in figure 3. These curves also indicate, when using sine-wave

exciting current, the difference in results from measuring the voltage with a repulsion-iron voltmeter which reads rms voltage, and the Rectox voltmeter which reads the average voltage multiplied by the form factor 1.11.

It will be noted that there is quite close agreement between the sine-wave voltage and sine-wave current excitation curves, when the voltage, in the latter case, is measured with a Rectox voltmeter. This is in accordance with accepted practice, as it is known, that for a distorted voltage wave having the same average value as a given sine wave voltage, the maximum flux is equal. The equal values of maximum flux represent equivalent flux conditions independent of wave shape.

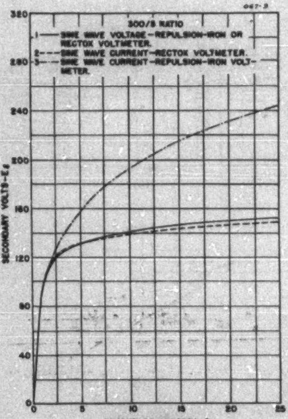

Figure 3. Saturation characteristic curves taken at sine-wave voltage, and at sine-wave current

Under operating conditions the primary current of the transformer is essentially a sine wave. Through the lower-density range the exciting currents, secondary induced voltages, and burden currents are all approximately sine waves. In the saturated region all of these quantities are somewhat distorted. However, the errors introduced by these harmonics are relatively unimportant unless they are large, and then only when the total exciting current is an appreciable portion of the primary current. These conditions are illustrated by the oscillograms of figures 4*a*, *b*, and *c*.

It appears from a practical operating viewpoint that saturation tests may be made independent of wave form when using rms ammeters and voltmeters responding substantially to average voltage but with an rms sine-wave calibration. Such data will give sufficient accuracy for most performance calculations.

Effects of Primary and Secondary Winding Locations on Performance

In an effort to determine the effect of and variations in the secondary leakage reactance of bushing transformers at high values of overload currents, conventional ratio and phase-angle tests were made on several oil-circuit-breaker transformers. The standard multiratio transformer has the total secondary winding well distributed over the core, but the various lower ratios are obtained by means of tapping portions of the secondary winding, resulting in relatively poorer distribution on the low and intermediate ratios.

From a theoretical viewpoint the variation of secondary leakage with the position of secondary winding is increased with closer proximity of the primary return conductor, with higher magnitudes of primary current, with greater asymmetry of the secondary winding, and with increased core diameters. In this investigation the transformers were tested with the approximate spacing of the primary conductor as encountered in practice, and with two different positions of secondary winding with respect to the primary return as shown by positions *AA* and *BB* of figure 9. Position *AA* represents the middle axis of the secondary winding in a relation to the return conductor which gives the condition of mini-

mum coupling, and likewise position *BB* gives a maximum coupling.

These tests, typical results of which are shown by figures 9*a*, *b*, and *c* are not sufficient in scope to establish definite boundaries for all of the parameters previously listed. However, for standard bushing current transformers with core dimensions and return conductor spacings encountered in conventional apparatus, and for primary currents up to 25,000 or 30,000 amperes, satisfactory results in calculations involving relay applications can be obtained when the secondary leakage reactance is neglected. This is particularly true when it is observed that most of such applications use performance data based on nonsaturating burden impedances, which is, at times, coarsely modified to meet actual operating conditions.

Various Forms of Saturation and Loss Curves

The saturation and loss data taken under the conditions previously outlined result in a set of data as shown in figures 5*a* and *b* for various ratios. The data thus taken can be shown in several different forms, and may be converted into similar data for any other ratio using the same magnetic core. Two forms are indicated by the curves of figures 5 and 6, and the methods which can be used for these conversions are given in appendix II. The first form gives voltage and watt loss versus exciting current in secondary terms for a given ratio, while the second form gives the core loss and magnetizing components on an ampere-turn versus volts per turn basis which is independent of the ratio.

Attention is directed to the curves in figure 5, where the full-line curves are plotted test data, while the indicated points on the 100/5 and 300/5 ratios are conversions from the 600/5 data using equations 10, 12, and 13 of appendix II. These curves indicate that very satisfactory transformations from one ratio

(*a*)—Simplified equivalent circuit of current transformer on secondary base

(*b*)—Vector diagram of (*a*)

to another may be made, the greatest source of variation coming from the use of commercial rather than precision testing facilities. Figure 6 is another form of expressing the data as calculated by equations 4 to 8 of appendix II. In this form they may be considered the master curves since they give the fundamental data which can be used to calculate the saturation and loss curves, and other calculations based on these data for any ratio using the same core. Since bushing current transformers have only the single primary turn, the ordinates for the magnetizing and loss ampere turns of figure 6 could be conveniently called primary amperes.

Calculation of Ratio and Phase-Angle Performance

The formulas for the calculation of transformer performance from the saturation and loss curves are given in appendix III. These calculations may be divided into two classes; the first giving both ratio and phase angle, and the second giving approximate ratio. In this connection it is interesting to note the theoretical effect of burden power factor on the phase-angle error of the transformer, as illustrated by figure 7. For lagging burdens the maximum possible phase angle error for any degree of saturation is less than 90 degrees and decreases with decreasing burden power factor, but in practice seldom exceeds 30 or 40 degrees. With unity or leading power factor burdens the phase-angle error may approach 90 degrees. Hence, for burdens having very lagging power factors the second method of calculation gives good results.

The agreement between the first method of calculation and test data is indicated in figures 9*a*, *b*, and *c* which show the comparison between calculated and actual test performance. As indicated, there is a difference between the results which occur for the following reasons:

1. Neglect of secondary leakage reactance which has been previously mentioned.

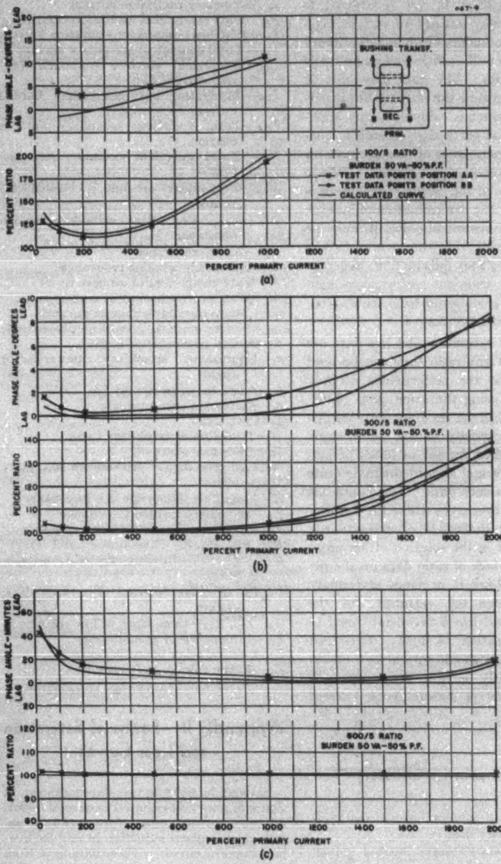

Figure 9 (left). Ratio and phase-angle calculated and test characteristic curves of current transformer

(*a*)—For 100-to-5 ratio

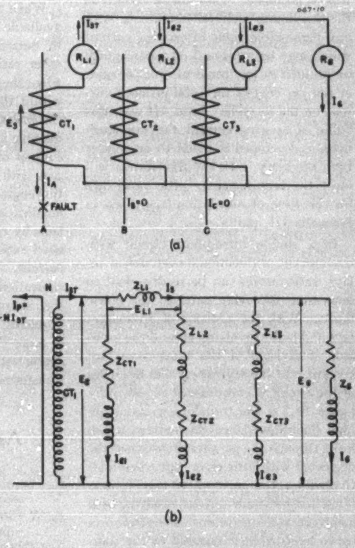
(*b*)—For 300-to-5 ratio

(*c*)—For 600-to-5 ratio

Figure 10

(*a*)—Typical three-phase relay circuit

(*b*)—Equivalent circuit for (*a*)



2. Neglect of harmonics, particularly with respect to their effect on the phase-angle error. The null test method used to obtain the phase angle compares the fundamental-frequency components of the secondary and primary currents, while the method of calculation has assumed all quantities are of fundamental frequency.

3. The order of accuracy of test data, including both saturation and loss data, as well as ratio and phase-angle data. Test errors could be reduced to a minimum by increasing the precision of the testing facilities. However, the work described herein was done with ordinary commercial testing equipment in order to observe the limitations which might be imposed on the use of saturation and loss data in practical applications.

Application to Relay Problems

In a large number of applications it is only necessary to determine if the degree of linearity of the transformer performance with a given burden over a specific range of primary current is within required limits. A glance at a saturation curve such as shown in figure 5*a* enables one to estimate quickly the limits over which approximately linear performance will be obtained. This can be defined as the maximum voltage obtainable with any permissible value of exciting current which may be expressed on a percentage basis, such as two per cent, five per cent, or ten per cent of the total primary current on the secondary base. If with this value of exciting current the secondary voltage developed is equal to or greater than necessary, then the transformer will meet the requirements. The procedure for this form of calculation is outlined in appendix III, part *c*.

In a simple three-phase circuit with overcurrent or directional overcurrent relays, ratio curves can be readily used to determine the relay settings for phase faults. With the addition of ground relays and faults involving ground the problem of division of the total secondary current into the several parallel branches of the circuit is encountered as shown by figure 10. If the transformer ratios are high (high impedance) the current which leaks through the parallel circuits may be neglected with little error, but when relatively low ratios are involved this problem often becomes quite serious, resulting with incorrect relay operation. The saturation curve lends itself admirably to the solutions of problems of this nature as outlined in appendix IV. It will be evident that additional refinements can be made on this method by taking into account the vector relationships and all of the circuit constants. Again, in cases involving the paralleling of transformers of two or more circuits, similar problems of leakage of the secondary current through the multiple circuits and the effective burdens are encountered.

Conclusions

From the foregoing it is evident that the open-circuit a-c saturation and loss data will be extremely useful in the field of relay application. It can be utilized to determine relay settings for various magnitudes of secondary burdens and primary currents, as well as ratio and phase-angle characteristics. The data may also be used to determine the range of linear performance, which is valuable in any application, and is particularly useful in comparing characteristics of transformers for differential protection schemes. Where a knowledge of the exciting impedance is required for the determination of leakage currents in branch circuits, it may be easily obtained from the saturation and loss curves. This information, like that required for transient performance, cannot be readily obtained from the conventional performance curves.

When the saturation and loss data are available on any ratio they can be used to determine the performance on any other ratio using the same core. Likewise, they can be used for any burden within the capacity of the transformer; the latter when defined in terms of permissible error and current range, is quite evident from such data. This is not the case with ratio curves where the application engineer, in the field, often is seriously handicapped in the solution of his problems by the lack of ratio data on the desired ratio, burden, or range of primary current. Since the versatility of the saturation and loss curves lends itself to the simplification of many diversified problems, they should appeal as a means of more clearly defining the overcurrent characteristics of bushing-type current transformers.

Appendix I—Glossary

E_{si}—Secondary induced internal voltage—secondary base
E_{si}/N—Secondary induced internal voltage—primary base
E_p—Primary terminal voltage
E_s—Secondary terminal voltage
E_s/N—Volts per turn
E_{sk}—Secondary voltage of transformer at a specified exciting current
I_sX_s—Secondary leakage reactance drop
I_pX_p—Primary leakage reactance drop
I_sR_s—Secondary winding resistance drop
I_pR_p—Primary winding resistance drop
I_s—Secondary burden current
I_{ek}—Permissible value of excitation current for a secondary voltage E_{sk}
NI_{ST}—Total secondary current—primary base
NI_S—Secondary burden current—primary base
I_{ep}—Core excitation current—primary base
I_{wp}—Core excitation watt component of current—primary base
I_{mp}—Core excitation wattless component of current—primary base
I_p—Primary current
I_e—Secondary excitation current
I_W—Watt component excitation current
I_M—Wattless component excitation current
I_{ST}—Total equivalent secondary current
I_{SX}—Equivalent wattless component burden current I_S
I_{SW}—Equivalent watt component burden current I_S
I_{XT}—Total equivalent secondary wattless current
I_{WT}—Total equivalent secondary watt current
X_{LE}—Equivalent secondary burden reactance
$(R_L+R_S)_E$—Equivalent secondary burden resistance
R_L—Burden resistance
R_S—Secondary winding resistance
F—Watt component of ampere turns
M—Wattless component of ampere turns
T_n—Times normal voltage or current
α—Primary-secondary current phase angle
θ—Burden power-factor angle
θ_1—Equivalent secondary power-factor angle
θ_2—Angle between E_s and I_{ST}
θ_3—Excitation current angle
ϕ—Core flux
N—Transformer secondary turns
W—Core loss watts
NI—Ampere turns—primary or secondary base
Z_T—Total secondary burden impedance
Z_S—Secondary burden impedance
Z_e—Open-circuit transformer impedance
R_{L1}, R_{L2}, R_{L3}, R_G—Line and ground relays
CT_1, CT_2, CT_3—Bushing current transformers
I_A, I_B, I_C—Line currents of a three-phase system
Z_{L1}, Z_{L2}, Z_{L3}—Impedance of line relays
Z_G—Impedance of ground relay
I_G—Ground-relay operating current
E_G—Relay voltage at I_G current

Appendix II—Forms of Saturation and Loss Curves

Saturation and loss test data as shown in figure 5, may be presented in several forms, all based on the ampere-turn excitation required for a given induction in any particular magnetic circuit. These data have been taken with open-circuit primary, reading the impressed voltage and watts loss at specified values of secondary circulated current. The induced voltage is taken equal to the impressed voltage, since the resistance drop of the winding is of small magnitude and becomes negligible when considered in its vector relation to the impressed voltage. The watt loss of the secondary winding is appreciable in comparison to the core loss and the observed data has been corrected to take this into account. Hence:

$$E_{st}=E_s \tag{1}$$

At a given voltage E_s for N turns, the exciting current is I_e, figure 5*a*, and the exciting volt-amperes are:

$$E_sI_e \tag{2}$$

At this current I_e the core loss is W watts, figure 5*b*. The angle between E_s and I_e as shown by figure 7*b* is θ_3 and is expressed:

$$\theta_3=\cos^{-1}\frac{W}{E_sI_e} \tag{3}$$

The exciting current is divided into its magnetizing and loss components I_M and I_W respectively:

$$I_M=I_e\sin\theta_3 \tag{4}$$

$$I_W=I_e\cos\theta_3 \tag{5}$$

The data may then be interpreted in values independent of the secondary winding.

$$\text{Induction}=\frac{E_s}{N}\text{ volts per turn} \tag{6}$$

$$\text{Excitation}=NI\text{ ampere turns} \tag{7}$$

The excitation in ampere turns is the same on either primary or secondary turn basis, and since the bushing transformer has only one primary turn it follows that:

$$I_{mp}=NI_M=M$$

and

$$I_{wp}=NI_W=F \tag{8}$$

By the use of equations 4 to 8 a set of data for a given ratio and core as represented by figure 5*a* and *b* may be converted into the general form as given by the curves in figure 6.

Another convenient form of interpreting these test data as obtained on one ratio N_1 to another ratio N_2 is shown by the curves for the 100 to 5 and 300 to 5 ratios in figures 5*a* and *b;* and is derived on the following basis:

For a given voltage E_{s1} and loss W_1 on turn basis N_1 with exciting I_{e1}:

$$N_1I_{e1}=N_2I_{e2} \tag{9}$$

Therefore:

$$I_{e2}=\frac{N_1}{N_2}I_{e1} \tag{10}$$

Likewise the induced voltage per turn:

$$\frac{E_{s1}}{N_1}=\frac{E_{s2}}{N_2} \tag{11}$$

Therefore:

$$E_{s2}=\frac{N_2}{N_1}E_{s1} \tag{12}$$

and

$$W_2=W_1 \tag{13}$$

By the use of equations 10, 12, and 13 the curves for the 100-to-5 and 300-to-5 ratios as shown by the indicated points in figures 5*a* and *b* are calculated and the agreement with test values is well illustrated.

Appendix III—Calculation of Performance Characteristics

(a) Ratio and Phase Angle

The calculations are based on the equivalent circuit and diagram figure 7, which refers all quantities to the secondary side and includes consideration of the vector relationships. Assume a burden Z_B at a power-factor angle θ, current I_S, and ratio N. The total burden Z_T includes the secondary winding resistance R_S. Hence:

$$Z_T=(R_B+R_S)+jX_B \tag{14}$$

$$\theta_1=\cos^{-1}\frac{R_B+R_S}{Z_T} \tag{15}$$

Also the secondary voltage required:

$$E_s=I_SZ_T \tag{16}$$

For this voltage the excitation current I_e is required and obtained from the saturation and loss curves. These currents are then separated into their watt and wattless components, and added vectorially as indicated in the equivalent circuit and vector diagram of figure 7, with the following equations:

$$I_{SW}=I_S\cos\theta_1 \tag{17}$$

$$I_{SX}=I_S\sin\theta_1 \tag{18}$$

The values for I_W and I_M are obtained from the curves of figure 6 for the induction E_s/N.

Therefore:

$$I_W=\frac{F\text{ (from figure 6)}}{N} \tag{19}$$

$$=I_e\cos\theta_3\text{ (from figure 5}a\text{)}$$

and

$$I_M=\frac{M\text{ (from figure 6)}}{N} \tag{20}$$

$$=I_e\sin\theta_3\text{ (from figure 5}a\text{)}$$

$$I_{WT}=I_{SW}+I_W \tag{21}$$

$$I_{XT}=I_{SX}+I_M \tag{22}$$

$$I_{ST}=\sqrt{I_{WT}^2+I_{XT}^2} \tag{23}$$

$$I_p=NI_{ST} \tag{24}$$

$$\text{Per cent ratio}=\frac{I_p(100)}{I_SN} \tag{25}$$

Substituting (24) in (25) and collecting terms:

$$\text{Per cent ratio}=\frac{I_{ST}(100)}{I_S} \tag{26}$$

$$\text{Per cent primary current}=\frac{I_p(100)}{\text{Rated primary current}} \tag{27}$$

Phase angle is:

$$\alpha=\theta_2-\theta_1 \tag{28}$$

$$\text{where }\theta_2=\tan^{-1}\frac{I_{XT}}{I_{WT}} \tag{29}$$

and θ_1 is given by equation 15.

(b) Simplified Method

The calculations are based on the equivalent circuit and diagram, figure 8, and assume all quantities to be scalar values in phase with the secondary current. These quantities are referred to the secondary side. The justification for this method is based on the fact that relaying burdens usually have low power-factor angles approaching the excitation angle. Thus the calculated results will indicate poorer ratio performance than obtained in service, and will disregard the phase-angle performance. Under these conditions:

$$E_s=I_SZ_T \tag{30}$$

where Z_T is obtained from equation 14.

The total secondary current is:

$$I_{ST}=I_S+I_e \tag{31}$$

where I_e is a value of exciting current obtained from a saturation curve similar to figure 5 for a given ratio N at voltage E_s. The primary current, per cent ratio, and per cent primary current are than obtained by equations 24, 26, and 27 respectively.

(c) Linear Performance Range

The determination of the linear performance range of a current transformer may be ascertained from a saturation curve by assuming an allowable percentage P of maximum primary current I_p for the core excitation current I_{ek}. The exciting current on the secondary base becomes

$$I_{ek}=\frac{I_p}{N}\times\frac{P}{100} \tag{32}$$

The value of voltage on the saturation curve corresponding to the current I_e for a given ratio N, yields a developed voltage E_{sk}. Comparing the burden voltage E_s at rated secondary current with the value E_{sk} indicates the number of times normal T_n, that the transformer will function linearly, or

$$T_n=\frac{E_{sk}}{E_s} \tag{33}$$

With I_p taken as the maximum primary current and $5N$ as the normal primary-current rating, then if, $T_n>I_p/5N$, the transformer provides linear performance over the considered range. If $T_n<I_p/5N$, this indicates that the ratio error is greater than the permissible assumed value P per cent and requires recalculation on basis of lower primary current.

Appendix IV—Application of Saturation Curve to Typical Relay Problem

A typical problem involves the relay protection of a three-phase circuit with grounded neutral using phase and ground-current relays as shown in figure 10. Assume line-to-ground fault current in phase *A*, and no current in phases *B* and *C*, then the equivalent circuit for the three-phase circuit is as shown in figure 10*b*. Current transformers CT_2 and CT_3 in series with their respective line relays form leakage-current paths in parallel with the ground relay which may appreciably reduce the current I_G in the relay.

Assume the ground relay tap setting requires an operating current I_G, and following the practice outlined in appendix III, part *b*, wherein all quantities were considered scalar and in phase, the following procedure may be used to determine the approximate value of primary current required to operate the relay.

$$E_G = I_G Z_G \tag{34}$$

Since Z_{L2} and Z_{L3} are usually small compared to the transformer impedance, they may be neglected thus avoiding the complication of using a cut-and-try method to determine the total value of $(Z_{L3}+Z_{CT3})$. The result of neglecting the impedance of these relays will be in favor of the ground relay.

$$I_{e2} = I_{e3} \tag{35}$$

These values may be obtained from a saturation curve such as shown in figure 5*a* for the voltage E_G on a ratio N.

$$I_S = I_G + 2I_{e2} \tag{36}$$

$$E_{L1} = I_S Z_{L1} \tag{37}$$

$$E_s = E_{L1} + E_G \tag{38}$$

It then follows that the required excitation current I_{e1} for CT_1 may be obtained as previously noted for voltage E_s.

Then

$$I_{ST} = I_S + I_{e1} \tag{39}$$

and

$$I_p = NI_{ST} \tag{40}$$

This last equation gives the approximate primary current required to obtain the ground relay current I_G.

Power Supply for Railroad Electrification and Fundamentals of Power Contracts

E. R. HILL
FELLOW AIEE

THE PURPOSE of this paper is to indicate and clarify the status of the American railroad as a major factor in the generation and use of power, the extent to which steam-railroad electrification has become an element therein, the effect of electric-power costs on the extension of railroad electrification, and the desirable features of power contracts in connection with such electrification.

Railroads as Producers and Users of Power

Before the advent of the electric street and interurban railway and the use of electricity for domestic and industrial lighting and power purposes, the railroads of the country were the large producers and users of power, of course developed in many relatively small steam-locomotive units. That power business has grown until in 1937 the aggregate indicated horsepower of locomotives in service on the 136 class I railroads (roads with operating revenues of more than $1,000,000 a year) amounted in round figures to 100,000,000 horsepower. This compares with an aggregate installed capacity of all utility plants—hydro and steam—of approximately 50,000,000 horsepower.

Extent of Railroad Electrification

There are approximately 250,000 miles of railroads in the United States of which 235,000 miles are in the class I group. Of this total only 1.3 per cent have been electrified (6 per cent in the rest of the world). This, however, represents a considerable mileage, namely 2,965 route miles (6,950 miles of track) distributed over 24 railroads. The main reason for this relatively slow progress is the high capital cost of electrification because of which operating savings do not result in a sufficiently quick payout to virtually compel electrification.

Advantages of Electrification

Electrification permits operating accomplishments that are not possible with steam power; it increases the capacity of a given railroad thus frequently saving large expenditure for additional trackage or terminal facilities; it adds to the attractiveness of the service and the comfort of the public; and through operating savings usually more than pays fixed charges. Thus it is conspicuous in being a type of railroad betterment that provides many desirable facilities and at the same time "pays its way." Among the outstanding operating benefits are great reliability of operation, high degree of availability and serviceability of the traction units, and the almost unlimited amount of power that may be made available for the movement of traffic. Underground terminals and connecting tunnels would be impracticable without electrification and capacity limitations of long mountain tunnels are overcome thereby.

Today probably the greatest demand on transportation is for service and the above advantages, together with the high operating speeds attainable, make electrification a valuable factor in enabling railroads to meet this requirement.

Operating Savings Due to Electrification

The major elements of operating cost, wherein savings by electric power as compared with steam are effected, include:

Locomotive repairs. These are considerably lower under electric operation and constitute one of the largest items of saving. Enginehouse expenses, inspection, etc., may be included in this general group and in these substantial savings are effected.

Transportation costs enter into the picture—these savings are substantial when the improved operation with electric power can be fully realized and the service can be rendered with a smaller number of larger train units.

Miscellaneous and indirect savings usually aggregate a substantial sum.

Cost of electric power versus locomotive fuel is an important item. Under some conditions this cost makes the project unattractive and becomes a controlling consideration from the standpoint of operating costs and savings.

Paper 40-27, recommended by the AIEE committee on transportation, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 28, 1939; made available for preprinting December 20, 1939; released for final publication March 21, 1940.

E. R. HILL is president of Gibbs and Hill, Inc., New York, N. Y.

Advances in the Art

The major advances in the art of power production as affecting efficiency and cost have been in the conversion of the heat energy in fuel into mechanical energy, where the efficiency has always been relatively low. The efficiency of conversion of mechanical into electrical energy is already high and little improvement has occurred or can be expected here.

During the period of great improvement in boilers, furnaces, and prime movers due to more efficient combustion methods, higher pressures, and superheat and other advances in the design of steam-electric generating plants parallel progress has been made in the efficiency of the steam locomotive. Thus in the past 15 or 20 years, there has been a reduction of about 25 per cent in the coal consumption on steam railroads per transportation unit. In the same period, as shown by the Federal Power Commission's statistics, there has been a reduction of nearly 50 per cent in coal burned per kilowatt-hour in steam-electric power plants of the utility companies. These figures indicate that in so far as efficiency of conversion of fuel into mechanical energy is concerned, the stationary plant still has the advantage.

Public-Utility Supply Versus Railroad Generating Plants

In the early days of railroad electrification, including that of terminals and certain city transit lines, it was found economical or necessary for the railroads to build their own power plants. The characteristics of the supply—frequency, phase, amount and fluctuating character of loads, etc.—and the rates quoted by utilities for such supply indicated in many cases that substantial savings would result from the railroad building its own plant. An important part of this advantage is that the railroad plant is built to produce the kind of electric power required without conversion from 60 cycles and it can be conveniently located with respect to the railroad's load center. Latterly, some of these plants have been leased or otherwise taken over by the utilities and purchased-power contracts substituted for railroad generation. In connection with most of the larger and more important railroad electrifications, power in whole or in part is now purchased from the utility companies.

Characteristics of Railroad Load

All railroads, both in the United States and abroad, use for traction purposes current of other characteristics than 60 cycles three phase that now is the general standard in this country for commercial power systems. This means that converting equipment of some kind is necessary to produce either direct current or 25-cycle single-phase current required for railroad operation. Development of the static converter type of equipment for frequency changing may result in increased efficiency of conversion and ultimately in lower cost of such equipment.

On the shorter railroad electrifications, such as for terminal operation or for mountain-grade lines, because of heavy train units and other operating conditions the demand on the supply system fluctuates widely. In some cases also the peak loads frequently occur at irregular and unpredictable times. These, together with the characteristics of the current, are adverse conditions which tend to make the supply by the utility of such requirements somewhat difficult and relatively costly.

On the other hand, where the railroad electrification is extensive and the traffic dense and comprised of a large number of train units, the fluctuations are not unduly severe and the load factor is relatively high; also the heavy demands frequently occur at off-peak times with reference to the utilities' commercial load. These features are favorable and should tend to reduce the cost of supplying energy.

Supply From Several Utilities

On extensive electrifications where the electrified lines cover hundreds of miles of route and cut across territory normally served by a number of different utilities, it is usually necessary for the railroad either to choose between such utilities and provide its own transmission lines in addition to substations and trolley system or to enter into agreements with two or more of the utilities. In the latter case, the railroad's entire requirements must be covered and the rates should be so applied that the railroad pays on the basis of its system load factor; otherwise it will be penalized in regard to load factor due to dissimilar conditions in the different areas traversed.

Table I

Service Operated	Miles of Route Operated	Miles of Track Operated	Average Monthly Demand*	Load Factor (Per Cent)
Suburban only	130	400	37,000	33–34
Through passenger service added	180	600	60,000	46
Same, with through passenger service extended	350	1,200	76,000	48
Same, with through freight added	380	1,370	120,000	55
Same, with further extension of through passenger and freight service	675	2,190	141,500	62

* Based on three maximum clock hours per month.

In this connection it is interesting to note the effect the extension of electrification has had on the load factor which in turn affects the over-all cost of energy as illustrated by table I.

This table shows, as is well understood, that the load factor of the supply to purely suburban electrified lines is low because of the heavy morning and evening travel and relatively light load at other times of the day.

When this suburban service is supplemented by through passenger traffic or by both passenger and freight, there is a substantial improvement in load factor. When the through passenger and freight traffic becomes so extensive and heavy as to form the major portion of the load an excellent load factor results. Thus in the table the average monthly load factor gradually increased from 33 per cent for suburban traffic only to 62 per cent after the entire program of suburban and through electrification was carried out. If there had been no suburban electrification the average load factor due to through passenger and freight service would have been of the order of 75.

If the electrification had been divided into say three main sections the load factor for each section would have been lower and the sum of the peak loads or demands on which separate billings would be based would be of the order of eight to nine per cent higher than the actual system peak loads. This in the case above cited would have represented an additional power cost to the railroad of more than $200,000 a year.

The supply of power by several utilities at the railroad's system load factor can be made effective in either of two ways:

1. By the railroad installing transmission lines of sufficient capacity to interchange power and energy between the different areas, thus enabling each utility actually to deliver its share or quota of the total demand and energy requirements, through the railroad transmission lines, or,

2. By the utilities jointly contracting with the railroad and with each other to supply

the portion of the demand and energy actually drawn by the railroad in each area and combining or pooling the demand and energy and jointly billing the railroad.

Such utilities should be interconnected and operated in parallel on the 60-cycle side so as to maintain synchronism effectively and thus avoid momentary interruptions in the supply when trains pass from one area to another. Most of the utilities are already normally interconnected for their own operating and economic purposes and their lines often parallel important trunk lines of railroads in territory where the traffic is sufficiently heavy to warrant electrification. In some localities portions of the railroad right of way are utilized for transmission lines of the utility. Joint use of railroad electrification structures is also feasible in some cases.

It is desirable from the standpoint of cost of special equipment that the number of supply points should not be unduly multiplied. Broadly speaking, the power-supply system—railroad and utility—should be so planned as to involve the minimum total capital expenditure by the parties consistent with the requirements of the service.

In considering electric traction railroads are confronted with the high capital cost and are usually desirous of shifting to the utilities as much as possible of the cost of power-supplying equipment. Locomotives are at present usually purchased through equipment trusts, the money being borrowed at favorable interest rates largely independent of the credit status of the railroad. If a similar plan could be devised for financing the roadway power equipment at favorable rates, greater progress in railroad electrification might result.

Cost of Electric Energy

It is generally believed that a public utility engaged in generating and supplying electric power to all sorts of customers should be able to produce power at lower cost than can be done by a railroad in its own power plant or plants; also that utilities are willing to supply the railroads on the basis of actual cost, including a reasonable return on investment and, therefore, there should no longer be any question as to whether a railroad about to electrify should purchase its power or generate it. There are a number of considerations, however, that enter into this question and which have an important bearing upon the railroad's decision to buy power from the utilities on such cost basis. Amongst these are the rates covering fixed charges on capital investment which the utilities may find necessary to use in arriving at cost and which may for a number of reasons be relatively high.

Such factors coupled with the railroad's ability to generate in its own plant, conveniently located, the form of energy required to operate its trains, may in certain cases more than offset the lower cost to the utility of generating its standard form of electrical energy and then converting it for railroad use.

The trend in the average cost per kilowatt-hour for purchased energy has been downward for the past ten years or more in respect to residential, commercial, and interurban and street-railway business. There was no definite downward trend in the cost of energy purchased for steam-railroad electrification until 1935 and since then the reduction appears to have been mainly due to improved load factor or some other special conditions rather than the lowering of rates.

Power Contracts

Experience has shown that power contracts as between railroads and electric utility companies in order to be generally satisfactory to the railroads should provide for the following railroad requirements:

(*a*). The contract should be for a long term—say 20 years with renewal options—so as to amortize on a low rate basis the cost of special equipment. A longer term than 20 years would be permissible if the rates for demand and energy are on a "cost" basis thus assuring to the railroad the benefits of advances in the art.

(*b*). The utility should preferably, although not necessarily, provide and own the special equipment and supply the power at the phase, frequency, and possibly the voltage required for railroad operation. This would minimize the investment by the railroad but fixed charges on same should be on a low basis comparable with rates applicable to the railroad's own capital expenditures.

(*c*). It is preferable to the railroad for the utility or group of utilities to supply power at a sufficient number of points in the electrified zone to take advantage of the utilities' networks to reduce investment costs by the railroad and at the same time further assure reliability of the supply.

(*d*). While the railroads would like to purchase power on a flat or sliding rate per kilowatt-hour, much as they purchase fuel, it has so far been impracticable to work out such a basis and separate demand and energy rates are customarily used.

(*e*). Demand charges should be on a monthly basis and should be established by averaging three or more clock-hour peak loads in the month. In selecting such peak hours, those caused by abnormal and emergency conditions should be excluded. System peaks rather than sectional peaks should be used in determining the maximum demand. When railroad peaks regularly occur at utility off peak times such as between 9:00 p.m. and 7:00 a.m., this should be reflected in a fair way in the demand rate.

(*f*). The energy charge should be based on the summation of meter readings at all points and is properly subject to correction for fluctuations in cost of fuel. The demand and energy charges may be on agreed rates or they may be based on the actual cost to the utilities within upset or over-all limits, the elements of such cost being defined, the rate used in billings in any yearly period being based on the actual cost for the preceding year.

(*g*). Where a substantial portion of energy is generated in hydroelectric plants of either the contracting utility or its affiliates and is furnished on a cost basis a suitable correction factor should be applied because of the high first cost and low operating cost of such plants.

(*h*). Power contracts should be as simple as possible as to form and should eliminate all unnecessary conditions and stipulations that might lead to misunderstandings and disputes. No guarantee as to load factor should be required of the railroad, nor should guarantees as to the minimum demand charge following a previously established maximum be required. While minimum loads of two-thirds or three-fourths of the previously established demands have been stipulated in some railroad contracts, it is preferable from the railroad's viewpoint to eliminate such clauses. Wide variations are inherent in the nature of the traffic on trunk-line railroads and are quite beyond the control of the management. They should be understood and recognized by the utility but should not appear in the contract.

In conclusion, the writer would express the hope that the downward trend in the cost of generating and distributing electric power will presently be reflected in the rates offered for railroad electrification and will be on a scale which will make the cost of power one of the major items of saving by electrification. It is also the hope that at the same time ways may be found materially to reduce the capital cost of electrification. If these things can be accomplished, important pending projects may be undertaken with every assurance of attractive financial as well as operating results. In that case, power companies operating in the vicinity of newly electrified railroad lines would be assured of large additional blocks of load, and the best interest of two important groups of public servants would be mutually advanced.

Discussion

Discussion will be found in the 1940 annual TRANSACTIONS volume and in the 1940 "Transactions Supplement" to ELECTRICAL ENGINEERING.

Restoration of Service on a Metropolitan Power System

W. C. BRYSON
NONMEMBER AIEE

A. P. HAYWARD
ASSOCIATE AIEE

THE purpose of this paper is to outline procedures and discuss pertinent problems that arise when restoring service to a metropolitan system following a major shutdown. In the discussion, consideration is given to the fundamental plan of the system, pointing out the inherent features in the design which prevent such failures. Several cases of trouble which have been the cause of service curtailment have been discussed and the service restoration procedure outlined. A brief outline of the essential procedure is given for two types of service restoration.

The conclusions and procedures discussed in this paper are the result of experience gained from failures which have occurred on the Duquesne Light Company system. It is recognized that the resultant procedures and conclusions may not be applicable to other systems. However, this paper does discuss many conditions which are common to all systems and therefore this paper may be helpful in formulating a service restoration procedure.

Description of Facilities for Supplying Load Areas

The power sources of the Duquesne Light Company system are comprised of three steam generating stations and two medium-capacity interconnections. The Colfax power station, which is located 18 miles east of Pittsburgh on the Allegheny River, delivers its 262,500-kw capacity to the 66-kv transmission system. The Brunot Island and Reed power stations which are located 4 miles north of Pittsburgh on the Ohio River, have a total capacity of 236,500 kw; use a common switch house; and, in general, supply the 11-kv and 22-kv load for the downtown Pittsburgh area and the industrial section adjacent thereto. All the power stations are directly connected to the 66-kv transmission system which acts as a high-capacity tie between the generating stations.

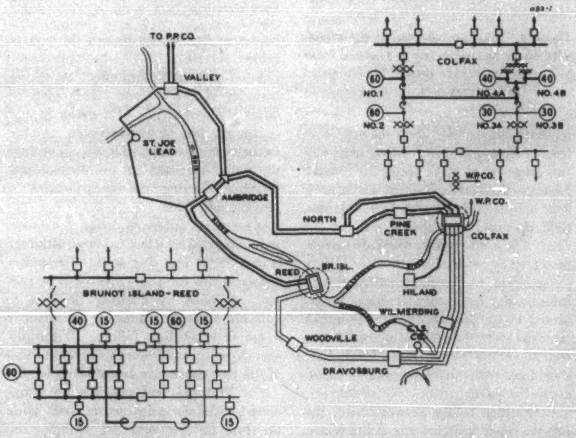

Figure 1. Schematic diagram of the Duquesne Light Company system

Inserts show schematic bus diagram of power stations

The 66-kv transmission system and the power stations normally have a running order that provides two segregated power systems which are referred to as the north and south rings. The 66-kv transmission system is essentially a ring surrounding the major part of the Pittsburgh territory having a secondary ring extending north and west along the Ohio River. This scheme provides a duplicate source to each of the substations located on the transmission ring. The sectionalizing of the system into a north ring and a south ring is accomplished by reactors between respective bus sections at the power stations (figure 1).

There are eight step-down substations on the transmission ring which feed definite load areas. In general, these stations feed isolated load blocks but are provided with secondary ties which are used for emergency power transfers. These substations are the source of the 22-kv feeds to the distribution stations supplying 4-kv service in the congested areas. They also supply the street railways and the high-voltage industrial service. In general, each one of these substations comprises a complete unit of the distribution system (figure 2).

The downtown Pittsburgh area and the industrial area adjacent to it are supplied from the Brunot Island switch house and are not directly dependent upon the 66-kv transmission ring. This area is supplied by a 4-kv radial system and a low-voltage network. The network system has four

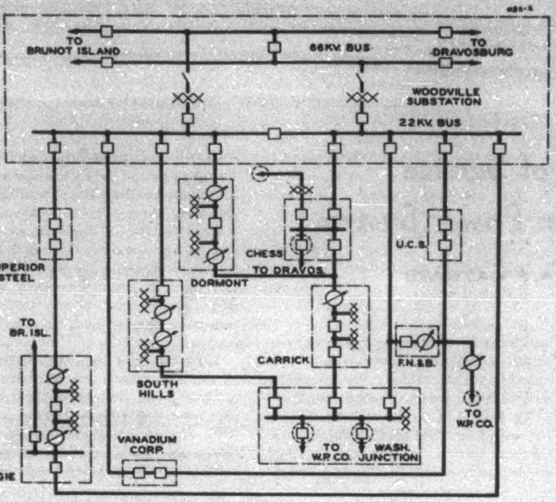

Figure 2. Schematic diagram of the Woodville 66-kv ring substation and related transmission circuits

separate areas, two areas having 4-kv feeders from downtown substations, and two areas fed at 11-kv from the Brunot Island switch house. Each 11-kv network area has its power source from bus sections operating on opposite sides of the ring. The feeds to these areas are further protected by connecting individual feeders to separate bus sections. The 11-kv cables which feed other services are connected to the Brunot Island bus in the same manner. The failure of a single bus section in the switch house, therefore, should not result in interruption of customers' service (figure 3).

In addition to the network load, the Brunot Island switch house is the source for various street-railway stations, and numerous high-voltage customers. The combined load in this 16-square-mile area reaches a maximum of 100,000 kw, 25 per cent of the system load. Due to the high load density in this area and the relatively short transmission distance, this service is supplied at the generator voltage.

The fundamental plan of the bulk power system involves its segregation into two main sections, commonly referred to as the north ring and the south ring. This provides ties between generating sources over two distinct and separate paths; and, due to the method of connecting the halves at the power sources through reactors, permits a fault to be immediately isolated with minimum effect on the remainder of the system. This plan reduces the probability of a major system shutdown due to transmission trouble. In the event of a ring split, the reactors in the power stations can be shunted out, thereby relieving the transformers of possible overloads.

A complete failure of a ring substation should only affect a limited area, although it may result in a ring split. The power requirements for these areas can be partially supplied by utilizing tie lines to adjacent areas, thus limiting the effect of a major substation failure. Transmission capacity is provided to cover the loss of one ring substation transformer bank.

The Brunot Island switch house is operated with two main bus sections, using the bus tie breakers to provide the emergency back up. Further protection is provided at the Brunot Island switch house by the isolated-phase construction.

Power-Station Auxiliaries

The layout of the auxiliary system follows, in general, the same plan as the transmission system. Two sources are supplied the duplicate equipments on each of the major generating or boiler units. One of these feeds usually has its source direct from the unit itself, while the remaining equipment has its source from other units or transformer banks connected to the opposite side of the transmission ring. Auxiliary power sources are provided by separate steam-driven station-service generators, station-service generators driven from the shafts of main units, or station-service transformer banks. This provides combinations consisting of either a house generator and a station-service transformer or station-service transformers supplied from opposite sides of the transmission ring. The separate voltage sources minimize the loss of auxiliaries due to disturbances on the transmission system. Station-service generators are available at the Brunot Island and Colfax power stations to assist in the initial start-up of these stations. The Brunot Island station-service generator, while not located in the Reed power station, is available for use at that location.

The major part of the station-service power supply is equipped with voltage-transfer devices which transfer the unit auxiliaries to a normal-voltage source in event of failure of the regular power supply. The voltage transfer eliminates the necessity of other types of reclosing. Simultaneous reclosing devices, provided to energize the auxiliary busses after a complete outage, do not appear advisable in many cases due to the characteristics of the auxiliary drives.

In addition to the general plan of sectionalizing all the main power sources into two sections, much effort has been expended in improving the bus construction and clearances, installing faster relays and circuit breakers, co-ordinating insulation, providing gas barriers and fire protection, and improving test and maintenance procedure, all with the intent to decrease the probability of failures.

With the ring substations responsible for the service of eight major load areas, and the Brunot Island switch house covering the requirements for downtown Pittsburgh and adjacent areas, the 66-kv breakers at the ring substations, or the 66-kv breakers at the power stations, have adequate capacity to restore these load areas.

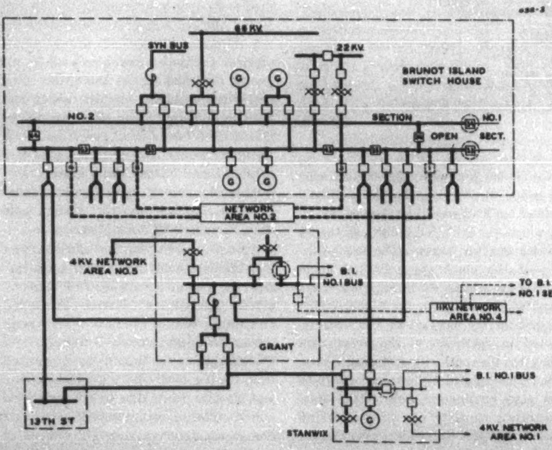
The low-voltage network presents a somewhat different problem and a master control switch has been provided at Brunot Island to reclose simultaneously any combination of breakers feeding each of the network areas. This simultaneous reclosing of each network area prevents de-energizing sections of the Brunot Island switch house for the purpose of reclosing the network through a bus-tie breaker. The simultaneous-reclosing scheme was easily applied due to the use of spring-operated breakers which eliminated consideration of control difficulties involved during simultaneous reclosure of solenoid-operated breaker mechanisms.

Major Operating Experiences

In discussing the operating experiences of the Duquesne Light Company which have involved an outage to a major section of the system, a brief outline of the type of loads served is necessary in order to visualize the response of the customers to service restoration.

The residential and commercial load, which is mainly lighting, is approximately 25 per cent of the total system load. The growth of refrigeration and air conditioning appear to be factors which will influence restoration of this service in certain areas. The industrial service, which comprises about 53% of the system load, includes much rotating equipment provided with low-voltage interlocks, the use of which prevents instantaneous pickup upon restoration of service. The remaining load is mainly street-railway service, which is supplied by synchronous converters or motor generator sets. This equipment is sensitive to system disturbances and generally requires manual restoration, except for a few unattended automatic stations. It is not unusual for a noticeable decrease in system load to occur following a severe voltage disturbance, due to the loss of synchronous equipment. It is believed that this condition is more favorable to rapid restoration of service than residential and commercial load, which approaches a resistance characteristic.

Figure 3. Schematic diagram of typical Brunot Island section and related transmission circuits



The major hazards which would involve a serious outage on the system fall into three classes:

1. *Electric Failures at Vulnerable Points on the System.* These involve failures either of bus sections in the power stations, transformer failures, or ring substation failures. These failures are the most frequent type of hazard, but, except for one or two cases which occurred many years ago, they have not caused other than a momentary disturbance to the system. The loss of one main generating unit is not considered a serious hazard as adequate spare capacity is normally available at all times.

2. *Loss of Transmission Facilities Due to Storms, Hurricane, or Sleet.* This condition would severely interfere with service but fortunately very little trouble has been experienced in the Pittsburgh district due to these causes. The geographical location precludes any great probability of a hurricane or tornado impairing the transmission system. The hazard from sleet is relatively great in this area. Severe sleet storms have not involved any important transmission circuits since 1925, although they have occurred frequently immediately adjacent to the Duquesne Light territory. Electrical storms are severe in this locality and have caused most of the major transmission failures.

3. *The Flood Hazard.* The flood hazard has been recognized and the system facilities have been installed to provide continuous service beyond what appeared to be a record flood. However, in March 1936 the most severe flood in the history of Pittsburgh occurred and resulted in an almost complete shutdown of the system; all but 2,500 kw of the entire system load was dropped. In the Pittsburgh district a flood does not present any serious hazard to the main transmission system, although it does affect many parts of the system serving industrial customers and domestic customers. However, due to flood conditions, these customers could not utilize the service if available. The generating stations, being in the river valleys, are subjected to the full brunt of the flood wave.

The most severe outage the system has experienced, except in the flood, occurred on Sunday evening, September 25, 1927, at 7:17 p.m. as a result of instability. Extending over a period of 31 minutes following the start of this disturbance, severe hunting existed between power stations and between generating units within the power stations. In order to restore stability to the system it was necessary to sectionalize the system, each area being fed by a separate generating unit with the load so proportioned as to come within the unit's capacity. The switching incidental to this split up was performed during the instability and resulted in immediate recovery following its completion. This disturbance resulted from a combination of factors which involved operation of the system below the normal voltage level while transformer taps were being changed to raise the voltage level of the 66-kv transmission system. This resulted in lower generator voltages which, combined with an error in the load forecast as a result of the changeover from daylight saving time, resulted in the instability. It is not expected that this condition will occur again from these causes due to the rigid maintenance of generator voltages and the operation of adequate reserve capacity.

There have been within recent years two major disturbances resulting from transmission-line failures which have upset the normal distribution of load in the transmission ring. On both occasions the 66-kv transformers at Brunot Island were tripped by the overload relays, isolating more load on the station than could be carried.

One major outage due to a transmission failure occurred on July 3, 1929. The primary cause of this disturbance was the failure of a ground wire on a four-circuit river crossing between the Wilmerding and Dravosburg substations on the south ring, splitting the south ring. This operation interrupted the normal power flow through this section which supplied part of the south-ring substations and the south-ring feed to the Brunot Island 11-kv bus. The interruption caused the power flow to seek a path across the reactor bus at Colfax along the north ring, through the 66-kv transformers at Brunot

Island across the 12-kv reactor bus and out through other 66-kv banks to the remaining substations on the south ring.

This redistribution of load caused severe overloads on the transformers connected to the north ring at Colfax and Brunot Island. The overload relays on the Brunot Island transformers connected to the north 66-kv ring tripped this bank, leaving 130,000 kw of load isolated on the Brunot Island station with 100,000 kw of capacity operating at 50,000-kw load. Due to the inability of the station to carry the entire load the frequency dropped to 56 cycles, reducing the load to approximately 110,000 kw. In a short time the steam pressure dropped from 190 pounds to 145 pounds and the voltage dropped from 11,600 volts to 10,200 volts. As a result of the low steam pressure the Brunot Island output decreased to 92,000 kw, indicating that it was necessary to quickly drop part of the connected load at this station in order to prevent the steam pressure from reaching a level where the station would have to be completely shut down. This is particularly important at this station, due to steam-driven auxiliaries for the boiler room and turbine room. The 66-kv transformers to the south ring and the transformers feeding the 22-kv transmission system were opened, relieving the station of all but the local 11-kv and low-voltage network load. The frequency and voltage recovered to normal and the station load settled at 75,000 kw.

With the frequency back to normal the station was immediately paralleled with Colfax through the north 66-kv ring and the 22-kv and 66-kv transformers reclosed. There were no difficulties experienced in picking up the load which was a result of service restoration. The nearness of this disturbance to noon hour resulted in a smaller total load than existed previous to the disturbance. The possibility of a simultaneous failure of any four-circuit transmission line is considered to be so remote that no precautions are taken to provide for this contingency.

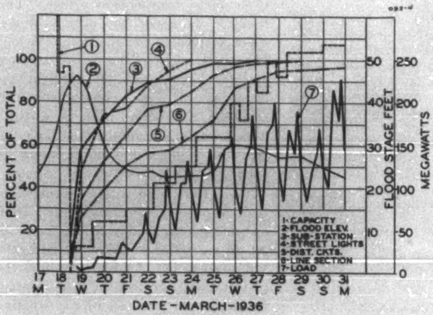


Figure 4. System condition following the 1936 flood

Another major disturbance due to a transmission failure occurred on August 13, 1935, at 9:11 a.m. This occurred at approximately the same relative location on the north ring as the south-ring disturbance just described and involved a double-circuit tower line. The conditions preceding this disturbance were abnormal, in that a 60,000-kw unit at the Reed power station was out of service for maintenance. Enough capacity was operating in the Brunot Island power station to protect against the loss of one of the 66-kv transformer banks, thereby providing backup for the Brunot Island local load. However, lightning struck this two-circuit transmission line and the resulting relay operations split the north 66-kv ring, routing the feed to the Valley district through the Brunot Island 12-kv bus and 66-kv transformers on the north ring.

Immediately preceding this disturbance the Brunot Island station output was 20,000 kw with 55,000 kw boiler capacity in service. The local Brunot Island bus load was 64,000 kw, 44,000 kw of which was being fed in through the 66-kv transformer banks. The sectionalizing of the north ring diverted about 40,000 kw additional through the south ring, which, added to the 44,000 kw required for the local 12-kv bus load, resulted in operation of the overcurrent relays on the south-ring 66-kv transformers. This isolated 104,000 kw of load on the same bus section with 55,000 kw of generating capacity operating at 20,000 kw. Under this tremendous overload the steam pressure dropped from 190 pounds to 100 pounds within one minute, and to 60 pounds within another half minute. A maximum load of 64,000 kw was observed on the Brunot Island station immediately after the stations had separated.

Immediately following the tripping of the south-ring transformer breaker at Brunot Island, the Brunot Island-Ambridge 66-kv lines were opened, relieving the generators at this plant of 40,000-kw load, in an attempt to restore the frequency in order to synchronize with Colfax. This load was immediately reclosed on the Colfax power station. After this relief, the Brunot Island generator load continued to decrease to 35,000 kw and then slowly decreased to about 22,000 kw, due to loss of steam pressure and failure of steam-driven auxiliaries. The frequency at this time was below 50 cycles, that being the lowest frequency scale observed and the bus voltage decreased from 11,600 to 7,500 volts. At this time, the Brunot Island 11-kv bus was de-energized and all generating equipment disconnected from the bus.

De-energizing the Brunot Island 11-kv bus resulted in a complete outage to the 23,000-kva low-voltage network load and all of the 11-kv and 22-kv transmission in the area adjacent to downtown Pittsburgh. Various 11-kv loads were sectionalized at Brunot Island during the disturbance and service was restored to the network and the remaining loads by energizing the 11-kv bus from Colfax through the north 66-kv ring transformers at Brunot Island. Preceding the restoration of network service, the Colfax power station load was 137,500 kw. Immediately upon re-energizing the Brunot Island station, which involved only the low-voltage network and a few 11-kv services, the Colfax load increased 56,500 kw to 194,000 kw. In the intervening period the remaining circuits, which had been sectionalized in an effort to relieve the Brunot Island load, were reclosed. By 9:42 a.m. the Colfax station load had increased to 252,000 kw. During this interval the generators at Brunot Island were synchronized on the system and brought up to 29,000-kw load.

At one interval shortly after service had been restored the station operators reported a total system load of approximately 282,000 kw between the usual 15-minute reading interval. This peak existed for approximately 5 minutes and was thought at the time to have resulted from the loss of diversity in refrigeration and elevator loads due to the extended period of the outage and some excess load due to simultaneous re-establishment of service by the high-voltage industrial customers.

These two cases of trouble involved a complete outage to relatively large blocks of load and yet in both cases when service was re-established there was no evidence that the generating equipment was unable safely to handle the load.

Since this last disturbance, generation and spare capacity has been allocated to the several load areas in such a manner that not only is the system protected for loss of generating capacity but each major load area is protected against loss of either generator or transmission capacity, except in the case of four-circuit tripouts.

There have been two other recent major electric failures which involved bus sections at the Colfax power station. In one case a 60,000-kw unit was completely crippled, due to a three-phase short circuit which destroyed an entire 12-kv bus section. The unit operating setup prevented these failures from interfering with the operation of the balance of the station, except for the voltage disturbances during the fault.

The most serious outage the system has ever observed started on March 18, 1936, as a result of the all-time record flood on the Allegheny and Monongahela Rivers. The flood stage reached a maximum elevation of 46.2 feet which was 36.2 feet above the normal river level. The highest previous flood, since the settlement in Pittsburgh, occurred, in March 1907, at which time the flood reached a level of 39.7 feet. Serious trouble was first encountered at a 39-foot stage about 4:00 a.m. on March 18. Preceding this time a few transmission and distribution circuits had been lost and most of the high-voltage customer stations in the low-lying industrial districts had been taken out of service at the customers' requests. Shortly after this flood water began to involve major substations and equipment. In rapid succession the 66-kv north-ring transformers at Brunot Island; the 11-kv control board at the Stanwix substation which feeds part of the downtown Pittsburgh district; and all system transmission and distribution services on Neville Island and adjacent districts along the Ohio River were removed from service. During this period the communication circuits were failing. By early morning contacts had been lost with many substations, the Brunot Island and Reed power stations, and the dispatching headquarters for the downtown distribution division and the substation division.

The operating problem during this period consisted of isolating faulted equipment and maintaining what service was possible on the remaining lines. About 7:00 a.m. the flood had reached the circuit-breaker mechanisms of the 66-kv line breakers at Colfax power station and the 66-kv and 22-kv line breakers at Brunot Island, making it impossible to operate any of the outdoor switching equipment and crippling the protective-relay system. However, this equipment was not removed from service due to failure of the control. When necessary, switching was done manually from boats. The system load reached its peak Wednesday at about 8:00 a.m. and decreased steadily after that time due to the flooding of customers' equipment. The loss of load on the system due to the effects of the flood reduced the system demand below the available capacity of the generating stations so that up until the time of shutdown there was adequate power for all essential services that were outside of the flooded areas.

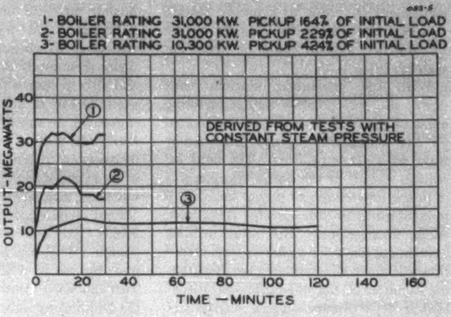

Figure 5. Typical stoker boiler response curves—constant steam pressure

Although the low-voltage-network areas in downtown Pittsburgh were practically all flooded, service was available until the system shut down. The submarine-type equipment withstood the flood with an insignificant amount of damage.

The Brunot Island station was the first generating station to abandon operation. The Reed power station was taken out of service at 11:20 a.m. due to flooding of the electric-bay basement. The turbine room was not flooded.

The Colfax power station continued to operate until 3:50 p.m. although a leak in the foundation which was adjacent to a field rheostat required removing from service a 40,000-kw unit at 11:37 a.m. This leak and some minor damage to the electrical equipment was repaired and the unit was about ready to return to service when it was necessary to shut down the entire station.

It was known for some time previous that there was little chance of averting a general shutdown. The 66-kv transmission system had been sectionalized so that the opening of a single breaker would drop a block of load. By this means the shutdown could be accomplished in an orderly manner without undue risk to the equipment at Colfax. It was also thought best to drop the load by opening a single beaker in order to forestall damage to customers' equipment which might result if operated at low voltage and frequency. The authorization to shut down was given at 3:47 p.m. following a rupture in one of the foundation walls in the Colfax power station. The dropping of sectionalized load areas proceeded and as the Colfax station load was reduced a generating unit was disconnected from the system by opening the main transformer breakers.

The first unit was off the line at 3:50 p.m., three minutes after the shutdown authorization was given and the last unit was off the line at 3:58 p.m., 11 minutes after the initial order. The station-service generators had been flooded by water entering the air ducts and were not available for some time preceding the shutdown. The total system load dropped was approximately 110,000 kw. This procedure was executed in remarkable fast time without any operating errors or any other event which in any way damaged any of the generating equipment or exposed the operating personnel to undue risk. All main equipment was de-energized before the flood water reached the insulation.

At this time several 22-kv transmission lines, which had previously been transferred to adjacent power companies, were carrying a load of approximately 2,500 kw, which saved the system from a complete shutdown.

The problem facing the operating organization at this time involved complete de-energizing of all the substation control equipment in order to conserve station service batteries until such time as the transmission system could be again energized.

With the generating stations shut down, the only possible way of restoring a few of the most essential services rested on the availability of the interconnections with other utilities. The need for station service at the power stations was of prime importance to permit immediate re-establishment of dewatering operations. While arrangements with other utilities were being made for power supply, attention was given to organizing the dispatching facilities of the substation and distribution departments. These dispatchers were moved to offices adjacent to the system operator to eliminate telephone congestion. These moves did not retard the rehabilitation work as no action could be taken until the flood waters had receded about ten feet. In the meantime the management formulated a "service priority list" to designate the order by which service was to be re-established. The list follows:

1. Communication
   - (*a*). Police and fire signal systems
   - (*b*). Telephone communication, including telegraph
2. Essential service, including cities, towns, and townships
   - (*a*). Water pumping
   - (*b*). Hospital service
   - (*c*). Dairies
   - (*d*). Bakeries
3. Street service
   - (*a*). Municipal street lighting
   - (*b*). Street cars (curtailed service only)
4. Newspapers
5. Domestic electric lighting
6. Commercial light and power
7. Industrial

Startup From System Shutdown

Before discussing any plans or sequence of starting up a system, it should be recognized that the cause of shutdown necessarily dictates the method of re-establishing service. With this thought in mind, two types of shutdowns will be discussed. The first case will have particular reference to the flood failure, which, briefly, is a type where total generating capacity is curtailed and cannot be immediately restored. A second case is assumed whereby some unforeseen electrical failure causes a complete shutdown, with the power sources, transmission system, and substations immediately available for service re-establishment upon isolation of the faulty equipment.

The system was shut down in an orderly manner in spite of the communication difficulties. This was due in part to instructions to all substations not to attempt reclosure in event of circuit failures and also to open and clear all circuits in event of loss of power supply. Prior to shutdown, arrangement was made with a local radio station to broadcast switching instructions to the Colfax power station, in the event of complete telephone failure, but these arrangements were not used.

First consideration was given to establishing station service to the Colfax power station. This was accomplished at 6:33 p.m. by use of a 22-kv interconnection with the West Penn Power Company to the Dravosburg substation. This station then energized Colfax through a 66-kv line and one of the main transformer banks. These banks were without their water-cooling facilities and were operated intermittently to prevent overheating.

The 66-kv interconnection with the Pennsylvania Power Company at Valley substation was energized next at 8:04 p.m. and Colfax transferred to this source. The West Penn Power Company tie was unavailable due to flooding of both the Colfax and Springdale switchyards.

Due to the flooding of the 11-kv cable potheads at the Brunot Island switch house, service could not be restored at this station until the cable terminals could be replaced, although a source of feed was available. The cable operation was complicated by the flooding of the 11-kv grounding-bank connections. The Brunot Island plant was completely flooded so that normal service facilities could not be used to dewater the plant.

The next major step was restoration of the Bell Telephone facilities in the downtown area served from the 11-kv network. This customer had a multiple-unit vault, one cable of which originated at Grant, and energizing the network feeder, all network transformers were stripped from the network feeder and the street main fuses opened at the Bell vault. The pickup of this service cannot be overemphasized, as its effect was immeasurable in insuring communication channels both for civic and company use.

On March 19, 1936, all load that had been restored was carried by the 66-kv interconnection at Valley and numerous 22-kv interconnections with the West Penn Power Company, each source serving isolated load blocks. At approximately 9:30 a.m. on this date, many substation busses and transmission lines were energized to facilitate service restoration to water-pumping stations, and other essential loads, most of which were served at 11 kv or 22 kv. At 12:15 p.m. additional capacity was added to the system by closing the Colfax-Springdale tie line to the West Penn Power Company. All load at this time was confined entirely to essentials, and the total system output limited to about 40,000 kw. In order to limit the service pickup to the priority list, a gigantic task was being performed by the distribution department in stripping the necessary circuits of non-essential load in order to limit the output to the interconnected capacity available.

On March 20, service was broadened to include some residential load, mostly rural, for the re-establishment of water supply. A total of about 30,000 kw was added in this manner, bringing the system output to about 74,000 kw.

Meanwhile, the power stations department was working to restore generating capacity, but was handicapped in many ways. At Brunot Island, for instance, the station was badly flooded and had to be dewatered. To accomplish this, a flood pump had to be moved in by a crane which required 500-volt d-c service. As the rotary converters at the Brunot Island station were inundated, service to the crane could not be established until a rotary converter was made available. By the time this was accomplished station service was available from the switch house through temporary leads.

The Reed power station, after drying out the coal-handling and circulating-pump equipment, was restored to service. It was necessary, however, to inspect and clean all the electrical connections in the Brunot Island switch house before power could be utilized from this unit. The boiler plant at Reed was kept on a live bank during the entire period, by permitting the coal reserve in the bunkers to drop to the floor and manually firing through the end doors, utilizing natural draft. The boilers supplied steam for a boiler feed pump which was temporarily modified to pump the seepage from the turbine room basement.

To fully appreciate the problem at Colfax, requires a brief description of the plant at the period immediately following shutdown. The flood water, while not affecting the turbines or generators, completely inundated the turbine-room basement crippling the main-unit auxiliaries entirely. In the switchyard, water had reached the 66-kv breaker mechanisms for the 66-kv lines and the West Penn Power Company tie line and had damaged practically all control cable.

At the time of the flood a 30,000-kw unit was being overhauled. All the auxiliary equipment below flood level that could be removed was moved above flood level thereby providing enough motors on another 30,000-kw unit to replace the flooded equipment. This made it possible to start the first 30,000-kw unit at 4:10 a.m. on March 22 about 84 hours after the shutdown.

In contrast to the other plants, Colfax had station service shortly after the shutdown. The boiler plant was completely down, and the first stoker-fired boiler placed in service about 39$^1/_2$ hours after shutdown.

At 5:15 p.m., March 23, the Reed number 1 unit was returned to service, increasing the system capacity. At this time the scope of pickup was expanded to include all available residential load. All distribution circuits outside of the flood area were cut in, and part of the load which had been stripped from circuits was restored. The pickup for this day amounted to about 50,000 kw.

The estimated demand at this point was about 20,000 kw in excess of capacity. This condition was set up to improve the load factor and with the intent of dropping any excess load over the peak period. During this period emergency overload ratings were in effect on all operating equipment.

The addition of generating capacity to the system required special relay settings and bus setups to protect adequately the equipment involved. These setups were too numerous to mention, but it is important to note that all equipment energized had some sort of protection provided. The system at this time was still segregated into several isolated load blocks with the largest block carried by the Duquesne Light Company stations. All of the available interconnections were still in use.

The load pickup was made along well-defined lines. As generating capacity was made available, a program was devised to bring the system peak load up to the available capacity. This was accomplished by preparing an hour-by-hour forecast of system load for the next day. As the system proper was still isolated into load areas, the load to be added was tabulated under the area affected and a total determined for the forecast. The aggregate of the areas gave a forecast for the system which was surprisingly accurate. Since the essential loads available were already connected, the forecast program assisted in determining the amount of excess power available in an area that could be prorated to the next succeeding service class on the priority list. On March 24 and 25 many industrial customers were reconnected on a restricted basis. As the generator capacity was increased, the isolated load blocks fed by various interconnections were transferred back to normal and by March 26, all services connected were on an unrestricted basis. At this date, however, there were many customers without service in the flooded areas.

After energizing the 11-kv bus at Brunot Island, the testing and energizing of the low-voltage network began. The transformers were cleared on all 11-kv feeders and the feeders tested individually from Brunot Island. With the feeders out, all transformer units unaffected by the flood were closed and the feeders closed at Brunot Island on a dead bus. The bus and network were then energized by closing an adjacent bus tie. It was necessary to conduct these tests with several cables and all available transformers to provide sufficient short-circuit current to clear a network fault.

Immediately following the return to service on an unrestricted basis on March 26, the emergency routing was rapidly converted into a heavy maintenance program. Figure 4 summarizes the progress of service restoration.

Station Pickup Capacity

There are several definite limitations that must be observed in determining the amount of load that can be picked up instantly and yet protect the equipment.

1. The load block that is to be picked up must fall within the overload capacity of the turbine and the steaming capacity of the boilers. The electrical equipment can usually withstand any load the turbine can deliver for a short time. Failure to observe this limitation will result in stalling the system.

2. The load pickup should not be so sudden or be such a large part of the available capacity as to cause priming of boilers with the danger of water carry-over damaging turbine blading.

3. The rate of load pickup on a turbogenerator which has just been rolled and synchronized must be held within the limits set by the manufacturer in order to prevent damage to the blading. This limit is usually about five per cent of the rating per minute. If the shutdown has been of short duration, the turbines which were carrying load preceding the disturbance usually will not have a rate of pickup limitation.

The boiler capacity in general sets the load conditions. Tests on individual boilers show that instantaneous changes in the steaming rate can only be realized when accompanied by a pressure drop using the accumulator effect of the boiler for the sudden increase in output. The curves (figure 5) show the rate at which the steaming rate is increased by an increase of the combustion rate. Powdered-coal boilers respond as shown and can hold the rating after the initial pickup. Stoker boilers are more uncertain in their performance due to the variation in condition of the fuel bed. A stoker boiler with a light fuel bed can produce a high rating for a few minutes but may not be able to hold the output until such time as the fuel bed can be built up for operation at the higher rating. This may require at least one-half hour before the ultimate rating is available.

Repeated tests have indicated that the following pickup ratings can be met in everyday operation. The standby boilers or boilers counted as having reserve capacity should be operated at not less than 15 per cent of their normal rating in order to keep the fuel beds ready for additional load. With this requirement met the boilers are then able rapidly to increase their output to 250 per cent of the initial output, provided the maximum rating of the boilers is not exceeded. The boiler spare capacity is based on this pickup ratio and the same ratio would apply for restoration of system load.

Theoretical studies have been made of boiler performance under these emergency conditions, but these studies, in general, indicate the optimum condition rather than the practical aspect.

One of the definite limitations in the pickup rate is personnel. An emergency load pickup greatly increases the attention required from the boiler operator; for instance, the feed water control is made semiautomatic to reduce the drum level as a preventative of priming, the dampers require resetting, and additional fans may be required. The coal feed is increased, the powdered-fuel boiler burners may require relighting if the auxiliary power supply was lost during the load drop. All these duties must be attended to manually and the rate at which the operating organization can accomplish these moves determines the degree by which the optimum rate of pickup can be reached.

Upon the occurrence of a major shutdown the several power stations immediately take such measures as may be required to hold what load is left or to protect the equipment. In general, the safety of the equipment takes precedence over system service, since once a disturbance has occurred any abnormal risks to equipment may result in further trouble which will require days instead of minutes to remedy. During the emergency the electrical switchboard operator becomes the key man in the stations, contacting the system operator, and advising the turbine and boiler-room operators of the system conditions and other information as fast as it is available.

The system operator is advised as soon as possible of the general conditions within the plant and furnished an estimate of the pickup capacity and the time required to perform this pickup. During this interval the station conditions will be returned to normal as fast as possible but no attempt will be made to restore service until all the elements contributing to service restoration are under control. Upon the sounding of the emergency alarm, certain picked maintenance men, who have had operating experience report to the turbine room, boiler room, and control room to augment the operating personnel and assist in the extra duties caused by the emergency. In event of loss of communication with the system operator, each plant will attempt to limit the load by opening lines, in order to retain reasonable steam pressures and prevent a general failure of the generating stations.

Experience so far has indicated that conditions on the transmission system and the time interval required by the system operators to co-ordinate the emergency activities retard the rate at which service is restored well within the limits of the power stations.

In order to start up a system which has been shut down, a plan or program must be provided. If, for instance, the flood hazard is great, a flood program is necessary. On the other hand, if shutdown is the result of failure unforeseen, the plan of pickup is determined by the remaining available facilities and the possible setup ensuing at the time. When a failure occurs, the operating personnel goes on its own, the load dispatchers, switchboard operators, and so on down the line must accept and share the responsibility of performing the duties required. Recognition must be made of existing rules governing operation such as overload ratings, equipment protection, and rate of pickup, and all these factors co-ordinated. In conclusion, past experience has proved the need for a pickup program. The major considerations necessary for making two types of plans for start-up are tabulated below and have proved invaluable in the restoration of service.

I. PREDETERMINED SHUTDOWN CAUSED BY FLOOD

Curtail service in an orderly manner, saving all equipment possible. This expedites the start-up.

Provide system operator with elevations of all equipment in flood area referred to river elevations.

Provide operating departments with detailed instructions giving the required work and material location for protection or salvage at incremental flood stages.

Establish communication facilities. It is necessary to enlarge existing facilities to care for increased traffic. Also emergency radio channels and adequate messenger service are needed. It is essential that boats and automobiles be provided for the messengers.

Provide station service to power stations. Standby interconnections, small oil-engine generator sets for lighting, and small power uses are essential. Steam-driven auxiliaries with stoker boilers are also desirable.

Provide a "priority of service schedule" with the necessary operating instructions to effect immediate restoration of service for public safety or health.

Provide a loading program based on the "priority schedule". This is based on the amount and character of the various service classes. Utilize restriction of service during emergency, either by municipal proclamation or appeal by company executives in order to widen scope of service restoration with limited capacity.

Establish operating personnel routine. It is necessary to provide a training program as part of operating routine to prepare for floods. During the emergency it is necessary to insure adequate food, safe water, and provide shelter and in some cases, clothing for employes. In addition it is essential that an immediate checkup be made of home conditions for those employes retained on duty.

Observe strict limits on total working hours to protect employes from sickness and injury.

II. SHUTDOWN CAUSED BY FAILURES NOT PREDETERMINED

Make a survey of system conditions immediately following a major shutdown of this type. This provides sufficient time to collect thoughts and avoids rash moves which may further damage equipment and thereby complicate service restoration. This further provides sufficient time to determine the status of the power plants and locate the failure.

Provide a plan of restoration. The plan will depend on the facilities available for operation. It is extremely desirable to maintain some firm boiler capacity to initiate the restoration plan. If possible, parallel a part of the generating capacity with available interconnections, and back feed power to the interconnection to establish firm plant capacity. When possible, parallel generating plants through the transmission system to increase the pickup ability. Restrict the rate of service restoration to avoid recurrent curtailment, and if required, segregate the system into load blocks which, when added, will not be in excess of the available turbine or boiler plant capacity. Co-ordinate the rate of service restoration with actual conditions of boilers and other essential power-plant equipment.

Establish a routine for operating personnel. Complete co-ordination is necessary between the load dispatchers and the switchboard operators. Provide plans for augmenting this personnel during emergency, and these plans should be predetermined and included in the operating routing. In conclusion, place complete confidence in the operating personnel to get out of trouble; they are intimately acquainted with their specific phase of operation, and can do the job best.

Discussion

Discussion will be found in the 1940 annual TRANSACTIONS volume and in the 1940 "Transactions Supplement" to ELECTRICAL ENGINEERING.

Restoration of Service From Large Metropolitan System After Complete Shutdown

H. A. DRYAR
ASSOCIATE AIEE

RAYMOND BAILEY
MEMBER AIEE

Synopsis: This paper sets forth briefly two general procedures that may be followed in starting the system of the Philadelphia Electric Company after a complete shutdown, and also gives some experiences relating to re-establishing service. There is also included an outline of some of the major principles of design followed in the development of the system which are important in minimizing the chance of a complete system shutdown and in facilitating restoration of service in the event of a complete outage.

It is believed that the problem of expeditiously restoring service from a system in the event it is completely interrupted may be divided essentially into two parts. The first has to do with operating routines which require that the operating men are thoroughly conversant with the many things that they are required to do at such times so that upon instructions from the system operator various activities in connection with restoring service will be carried out with little or no confusion. Needless to say, the process of restoring service is much easier when the layout, both in the stations and in the connections between stations that comprise the backbone of the system is not complicated and has a high degree of uniformity.

The second part of the problem of restoring service has to do with the maximum size of the block of load that must be picked up at one time, which if very large may cause trouble due to automatic opening of circuit breakers or difficulties due to the steaming rate of boiler plants not increasing rapidly enough.

Fortunately, in the case of the Philadelphia Electric Company, there are no single blocks of load large enough to make this a real problem. The largest of the three networks in the central business district of the City of Philadelphia has a peak demand of only about 10,000 kw. The load of the Pennsylvania Railroad Company, while slightly exceeding 100,000 kw, can be split into two parts for the purpose of re-energizing. In this case it is believed that the load will build up to the figure of approximately that before the interruption occurred over a period of several minutes as the trains get under way. The load of the Philadelphia Rapid Transit Company, which is of the order of 100,000 kw, is supplied from a number of different locations and therefore presents no problem in restoring service.

For the reasons outlined in the preceding paragraph, this paper will concern itself mainly with principles of design followed and development of the system in order to facilitate restoration of service, and to the operating procedures followed in order to re-establish service as quickly as possible.

Description of Bulk Power System

The bulk power system of the Philadelphia Electric Company (see figure 1) is that of a divided arrangement of the 66-kv and 220-kv transmission facilities into two backbones of the system; parallelism of the two distinct high-voltage systems being effected on the 13-kv busses through the transformers at the major load centers of the Philadelphia Electric Company and on the 66-kv ring bus of Christiana substation (Wilmington) and the 66-kv busses of Deepwater station. At Conowingo hydro station, the divided arrangement of the 220-kv transmission facilities extends to and includes the 13-kv generator busses.

The major load centers of the Philadelphia Electric Company are the steam generating stations and large high-voltage step-down substations. From these load centers energy is transmitted to distribution substations and to customers having high-voltage service. Customers of this type are also supplied from distribution substations.

The distribution of the generating facilities of the company among the major load centers is such that a satisfactory balance of the generating capacity and area load in each load center is obtained. The comparison of generating facilities and load of each load center is given in table I.

The capacity of the transmission facilities between all load centers, generating, and high-voltage step-down transformer stations, is adequate to make generating capacity of one area available to another for economical system operation or as reserve coverage in providing for the possible loss of generating equipment on any part of the system.

Principles of Design

Some of the general principles of design that are followed are enumerated in the following paragraphs:

1. Generating capacity is provided as close to the load areas as economics and other conditions make practicable, or in other words it is the desire to make each load area as nearly self-sustaining as possible under the circumstances encountered. In the case of generation by hydroelectric plants this is obviously not possible, due to the location of suitable sites being some considerable distance from the load.

2. Simplicity of layout. It has been the practice of this company for a great many years to avoid complication, both in the stations and in connections between stations, in view of the many advantages thus to be obtained.

Table I. Generating Capacities of the Various Load Centers and Approximate Amounts of Load That May Be Supplied Through Each Center

	Generating Capacity (Kw)	Area Load (Kw)
Richmond	255,000	180,000
Delaware	183,000	137,000
Chester	126,000	130,000
Deepwater	58,000	40,000
Schuylkill	179,000	170,000
Paschall		20,000
Conowingo	252,000	3,000
Plymouth Meeting		25,000
Westmoreland*		100,000
Barbadoes Island	45,000	75,000
Total	1,098,000 kw	900,000 kw

* Westmoreland load area included here as in Conowingo load area for the purpose of restoration. Normally it is part of the Richmond-Delaware area.

3. The system is so sectionalized as to minimize the effects of faults. As pointed out, the portion of the system operating at 66 kv is operated to all practical purposes as two separate 66-kv systems, which are interconnected at certain points mentioned earlier in the paper. The operation of the 66-kv system in this manner not only gives lower short-circuit duty on switchgear, etc., but minimizes the disturbance produced under such fault conditions. The sectionalizing of the system is further planned so that failure of any one locality should not reduce the capacity available to carry the load in this particular area below that required for the load involved.

4. Quick clearance of faults. Very much has been done, particularly in recent years, in reducing the length of time required to

Figure 1. Bulk power system of the Philadelphia Electric Company

In addition to the generating capacities shown in this figure the company has available a capacity of 62,000 kva in the Deepwater plant, which is owned jointly with the Atlantic City Electric Company. At the locations marked with an asterisk busses not normally energized have been omitted for the sake of simplicity. Certain stations of other utilities and the lines connecting with them are shown with broken lines

clear faults on those portions of the system where quick clearing is important. This involves the use of pilot-wire relays on 66-kv cables, differential protection of busses and transformer banks, and for certain applications circuit breakers that will clear a fault within eight cycles (0.13 second).

5. Isolation of equipment. Considerable attention is being given to the arrangement of equipment in switch houses, provision of barriers, etc., to provide a proper degree of isolation in the event of oil fires, explosions, etc. There is now under way complete modernization of the Schuylkill switch house which changes the layout from the present double 13-kv sectionalized bus to a six-section sectionalized ring bus with modern switchgear at the sectionalizing points and at several other important locations. It is believed that a layout of this type should do much to minimize the amount of capacity affected in the event of a fire or explosion. In the case of outdoor substations considerable attention is given to the location and spacing of equipment so that in the event of a failure it will not affect other equipment which is used for reserve purposes.

6. Interconnection. The most important of the interconnections of the system of the Philadelphia Electric Company with other companies is the 220-kv interconnection with the Pennsylvania Power and Light Company and the Public Service Electric and Gas Company of New Jersey. This interconnection not only provides advantages in the way of economy of operation, generator reserve, etc., but is extremely useful in the event of an emergency.

Starting Generating Station From Shutdown State

It has been indicated that each load area of the Philadelphia Electric Company system is adequate unto itself in generating capacity. Thus restoration of the system load should a complete shutdown occur may be a matter of starting each individual station, restoring the area loads and then paralleling the sections of the system to return to normal operation.

The restoration of each generating station is usually dependent on the supply to the auxiliary light and power busses. This supply, in the event of any station shutdown, may be provided by an electrical feed from an outside source. Failing this, the thermal capacity of the boilers in most of the stations is such that it would be possible to start up the auxiliaries and even a main unit. Thus, steam-driven d-c sets can furnish power for stoker drive and for emergency lighting; a Duplex circulating-pump set can be operated as a generating unit of 200-kw capacity and supply stoker sets, and fans and steam-driven oil pumps can be operated to restore oil-fired boilers. In one station a house turbogenerator is available to carry auxiliary load.

In instances of an individual station shutdown, however, an electrical feed from an outside source would usually be available for supply to the station auxiliary light and power bus and other than the usual starting measures should be unnecessary.

The supply to the electrical auxiliaries of Richmond station is indicated in figure 2. The electric auxiliaries in the other steam stations are supplied from transformer banks stepping down from a 13.2-kv bus and there are no transformers connected to the generator leads and no house turbogenerator.

Restoring the Station Load

When an operating bus has been subjected to an interruption, the bus is cleared; that is, all bus circuit breakers are opened. As the generating sources are restored to the bus, the outgoing lines are gradually restored and at no time will the capacity of these lines exceed that of the restored generating capacity. The operators in distribution and industrial substations restore their load gradually not exceeding the capacity of the lines made available to them.

Speed of Load Restoration

The restoration of the load should not proceed too fast for the boiler operators to handle. Delay may arise, however, if the dead busses are not cleared immediately after the interruption, as the simultaneous energizing of a number of large transformers and an appreciable amount of load from one source may cause a severe drop in voltage. This might result in the loss of auxiliaries such as boiler feed pumps and fans. As an instance, at the time of the complete system shutdown of April 4, 1937, the Schuylkill, Chester, and Wilmington areas were simultaneously closed to Deepwater station within a few minutes after the initial outage. The load of these areas just previous to the outage was approximately 90,000 kw. During the interruption, Deepwater station continued to supply the load of the Atlantic City Company and of the Du Pont Manufacturing Company, the combined load being approximately 40,000 kw. When the transformer equipment and considerable of the load of the three areas were simultaneously restored on Deepwater station, the voltage surge caused the loss of a boiler feed pump and the drop in steam pressure delayed the restoration.

In the initial step of restoration, the load of Deepwater station increased from 40,000 kw to 100,000 kw, Deepwater thus picking up all but 30,000 kw of the normal load of the three areas. The steam pressure at Deepwater station fell to 930 pounds, and 19 minutes elapsed before normal pressure, 1,300 pounds, was restored. The load of the three areas required 20 minutes to return to normal.

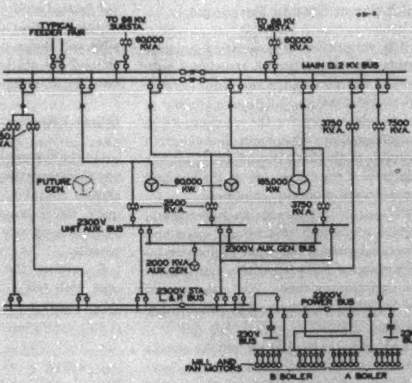

Figure 2. Auxiliary power layout for Richmond station

This station is the only one on the system of the Philadelphia Electric Company that has a steam-driven house generator

If the bus of each load area had been cleared, the restoration could have proceeded in successive steps rapidly effected as pilot lights indicated the lines had been re-energized.

Operating Procedures

Either of two methods may be followed in starting up the system after a complete shutdown and the choice of method may depend on the normal system load at the time of outage and the generating capacities that had been in operation just previous to the disturbance.

If, for instance, the shutdown occurs in the early morning hours, when Richmond, Schuylkill, and Deepwater stations had been operating at minimum loading, and Conowingo hydro station had been delivering maximum output, the procedure would be as follows, all stations having cleared their dead busses when the outage occurred.

1. Conowingo hydro station; bring all hydro units to synchronous speed.

1*a*. Deepwater station will energize lines to Christiana substation.

1*b*. Christiana substation will energize lines to Chester station and restore its 11-kv load.

1*c*. Chester station will energize its 66-kv busses and 13-kv bus from the Christiana substation 66-kv lines and restore its load.

2. If pilots are not received on 220-kv lines at Conowingo one minute after outage, all units will be closed to bus and both 220-kv lines to Plymouth Meeting substation will be energized.

3. Plymouth Meeting substation will restore the 66-kv lines to Westmoreland substation and Barbadoes Island station, and restore 33-kv lines.

4. Plymouth Meeting substation will parallel with the 220-kv interconnection.

5. Westmoreland substation will energize 66-kv lines to Richmond and Schuylkill stations.

6. Westmoreland substation will restore its 13-kv lines including the Delaware station tie lines.

7. Richmond station will restore its 66-kv and 13-kv lines including the Delaware station tie lines.

7*a*. Delaware station will restore its load on the first group of tie lines to receive a pilot, and then parallel the second group of tie lines.

8. Schuylkill station will energize the 66-kv lines to Chester station and its 13-kv lines.

9. Chester station will restore the system to parallel operation by synchronizing the Schuylkill station and Christiana substation 66-kv lines.

10. Other generating capacities that had been in operation may then be restored.

If the shutdown occurs during a heavy load period the restoration may be effected by each generating station restoring the load of its own area. When this is done, the sections of the system will be paralleled to establish normal operation. In such outages, there is one important rule; namely:

"Clear the dead bus."

As has been mentioned, this means that all circuit breakers of the dead bus must be opened. In restoring the lines and apparatus, this practice will avoid a repetition of the fault without being aware of its location and will prevent a voltage disturbance and the confusion that may arise if too much load is re-energized when the first unit is closed to the bus. The control of the return of the load also may be more satisfactorily maintained in this manner.

Initiative of Station Personnel

The restoration of generating capacity within the station to full speed and voltage is a function of the operating personnel of that station. The availability of an outside supply for the starting of the station auxiliary equipment, however, is a function of the load dispatcher, as is the direction of the energizing of the bus and the restoration of outgoing lines.

Co-operation between the boiler room, turbine room, and switchboard operators of necessity and through the realization by each group of their respective functions is of automatic response. The personnel of the boiler room knows that the station output must be restored to what it was before the disturbance and they also know what their part in the program must be. The personnel of the turbine room are also familiar with their responsibilities and this is also true of the switchboard operators, for the operations all of these men must perform in an emergency are similar to their everyday functions.

It is in the location, inspection, and isolation of faulted equipment that a high degree of initiative is very essential. The confusion that usually attends this type of station failure is usually the cause of undue delay in restoring the station to operation. The electrical supervision must first of all observe the essential safety regulations and see that none of the equipment in the area being inspected is energized until all men have left the scene. His inspection is primarily to determine what equipment may be re-energized and what switching must be done to isolate the faulted equipment. The performance of this function as expeditiously as possible will mean usually that the restoration of the station will be effected without any unnecessary delay.

Other Effects of Shutdown

On the system of the Philadelphia Electric Company the procedure in starting up after a complete shutdown does not require any changes in relay settings or alterations of any nature in the protective scheme.

Regarding the possibility of interference with telephone and signal systems, this is present for the duration of the fault and, in some of the past occurrences, has resulted in trouble on the circuits of a railroad company but has had no apparent effect on the leased telephone communication circuits used by the company.

Conclusion

The possibility of a complete shutdown of the system of the Philadelphia Electric Company is extremely remote, particularly as a result of changes effected in operation and design during the last two years.

The starting up after a complete shutdown, if it should occur, may be effected by starting each individual station separately as the generating capacities and the load of each major distributing center approaches a balance.

The restoration of all but the 25-cycle railroad load should usually be effected within five minutes, and the entire system within ten minutes, provided the functioning of the operating personnel is satisfactory.

So far as can be foreseen at the present time, it is expected that the design of system extensions will follow the same general principles now in use, except that sectionalized ring busses will likely be used more generally in the future instead of double busses.

Discussion

Discussion will be found in the 1940 annual TRANSACTIONS volume and in the 1940 "Transactions Supplement" to ELECTRICAL ENGINEERING.

The Design and Operation of a Metropolitan Electrical System From the Viewpoint of Possible Major Shutdowns

S. M. DEAN
ASSOCIATE AIEE

Synopsis: The bulk power system of The Detroit Edison Company is designed and operated in five power-plant load areas. These load areas are "loose linked" to prevent uncontrollable trouble in any one of them causing a total shutdown.

The internal design of the load areas is arranged to permit of ready sectionalizing in event of serious area shutdowns, thereby permitting the load to be picked up in small pieces. Such sectionalizing is practicable because the distribution lines are largely radial, that is, are not connected together beyond the substation.

A limited amount of experience data are given on the behavior of generators under instantaneously applied loads.

The rationale of emergency operating is developed and the special instructions outlined.

DESPITE the efforts of central-station operators and designers to the contrary, there occasionally occurs a complete shutdown of an entire major electrical system or a large section of one. Unless, in the design and the operation of the system, proper account has been taken of such a contingency, it may prove very difficult to again "start up" the system and unnecessarily long service outage may result.

Accordingly, it was felt that a symposium covering the design and operating practice of several large systems with respect to "starting up" would prove helpful to those facing such a problem. It is as a part of such a symposium that this paper is presented.

In any particular situation the difficulty of starting from complete shutdown, turns in the last analysis on the degree to which the load itself may be divided into discrete pieces, small enough to be picked up by the available generating capacity.

General

On a system where the load consists largely of primary or secondary networks it is desirable, in the interest of economy, to make the individual blocks of load or "pools" as large as can, with certainty, be picked up by the generating capacity available and by the number of feeders which the operators can simultaneously close onto the busses. In the design of such a system it is necessary to have a fairly accurate idea of the performance of generators under suddenly applied loads or overloads, and also how the load may be expected to vary with reduced voltage and perhaps reduced frequency. While some testing and a great deal of calculating have been done, the most reliable knowledge must of necessity come from the actual experiences of systems under emergency conditions and one of the principal purposes of this symposium is to bring forth reliable experience data of that kind.

On the other hand, in a system employing radial distribution lines beyond the substation, that is, lines which are not connected together, the load is already divided into relatively small pieces which can, if necessary, be picked up one at a time in detail.

Accordingly, the approach to the "start up" problem is determined by the character of the load area served and becomes a question of designing to meet the particular situation.

With the exception of a square mile or so, the territory of The Detroit Edison Company lends itself to the use of radial overhead distribution lines. Very few of the radial circuits have loads in excess of 1,500 kilowatts. Thus, there is no problem in picking up the individual circuits. In fact, in most cases, there is little difficulty in picking up whole distribution substations. Accordingly, this paper will be largely confined to the design of the metropolitan system to restrict shutdowns to limited areas and to the emergency operation of such a system.

The Bulk-Power System

Fundamental Design

To guard against the possibility of total shutdowns, the design of the bulk power system of The Detroit Edison Company is based on two principles.

The first principle is that the system shall be divided into several load areas (at present five) so interconnected that, should an uncontrollable fault persist in any load area, this area with its prime power source will disconnect itself from the system, thereby permitting the remainder of the system to go on its way. Also, each load area must, within reasonable limits, be self-sustaining since it may have to start up by itself and perhaps run that way for a time. This principle has been dubbed "loose linking."

The second principle is almost corollary to the first and is, that with any load area disconnected the remainder of the system shall be self-sustaining, that is, shall be able to carry its load at normal frequency and voltage.

Figure 1 is a diagram of the bulk power system of The Detroit Edison Company. You will note that there are five power-plant load areas held together at what are termed "interlinking points." Each "interlinking point" is indicated by a small rectangle with a diagonal line drawn through it. The solid black rectangles represent the ones in use at the time and the open rectangles the alternates.

While the design principles outlined above appear simple, there are several implications which in practice call for care in design as well as in operation. The first implication is that, since an uncontrollable fault is one which is not cleared by the normal protective equipment, the operation of the system sectionalizing circuit breakers at "interlinking points" must be delayed until the internal protective gear has had opportunity to clear the fault if it can do so, that is, until the fault has really become uncontrollable. (Needless to say, several successive steps of protective gear must have simultaneously failed before a fault becomes uncontrollable.) This necessary time delay at the interlinking points may amount to several seconds which might be troublesome to the other load areas from the point of view of stability of generators. Therefore, it is necessary to have sufficient impedance in the interlinking ties so that, under the worst fault conditions, the voltage in neighboring

Paper 40-30, recommended by the AIEE committee on power generation, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 24, 1939; made available for preprinting December 20, 1939; released for final publication March 30, 1940.

S. M. Dean is chief assistant superintendent, electrical system, The Detroit Edison Company, Detroit, Mich.

In the preparation of this paper, the author is indebted for indispensable information and comment to H. W. Collins, G. H. Doan, T. R. Halman, B. R. Moore, and H. C. Reasoner, all of The Detroit Edison Company.

areas will not fall low enough to cause generator instability in those areas. Based on calculations and such experience as we have had to date, the amount of the line impedance necessary to control short-circuit duty appears to be enough to accomplish this. So far, there has occurred one case of bus trouble which operated the interlinking points of its load area. No generator stability troubles occurred either in the faulted load area or any of its neighbors.

Another implication of these design principles is that the load included in any load area must be adjustable to the amount of generating capacity available to the load area. Not only must these conditions be met at peak load, but the system must sometimes be altered to meet the various generating requirement throughout the day. This may be particularly true during light load periods when the more economical plants are favored as to loading.

Further reference to figure 1 shows the bulk power system as it has been worked out to meet these conditions.

As an illustration of how load areas are adjusted, refer to the Conners Creek load area. At present, that plant is well built up with high-economy generating equipment. You will note from the position of the interlinking points in use, the black squares labeled *A*, that the load area is now widely extended. During the rebuilding period at Conners Creek, it was at one time contracted to the condition shown by the interlinking points labeled *B*.

An interesting variant of this principle exists at the Trenton Channel plant. There the plant operates in two parts, each of which serves a separate load area. It was relatively easy to make several of the generators "double throw," so to speak, and thus make them available to either load area. Thereby, we can, within limits, adjust the generating capacity to the area load, and we therefore do not need so great a proportion of transferable load to maintain the load areas on a self-sustaining basis.

Summarizing briefly, while we contemplate the complete shutdown of only one power-plant load area at a time, nevertheless each of the areas could be started simultaneously from standstill if necessary. Accordingly the problem of starting up becomes, for this system, one of the internal design of the load area.

Load Area Internal Design

Figure 2 shows the internal arrangement of a typical city power-plant load area, that is, where 24-kv underground transmission is used.

By a series of heavy dotted lines there is shown the physical segregation of the equipment and lines into zones extending from the generating station to the customer. Within these zones the radial distribution lines may be picked up one at a time if necessary to aid in restoring service.

Beginning with the generating plant, you will note that the generators and the tie cables to the adjacent plant areas are held together by a star-connected synchronizing bus and its reactors *S*. The synchronizing bus and reactors are carefully segregated from all other bus and switch rooms for the purpose of protecting them from the troubles arising elsewhere in the switch house. Next you will note that each set of generator switches and its "feeder gangs," as well as each set of tie line breakers *G*, is separated from the others by careful sectionalizing of the switch house. Also, the busses and all connections are completely

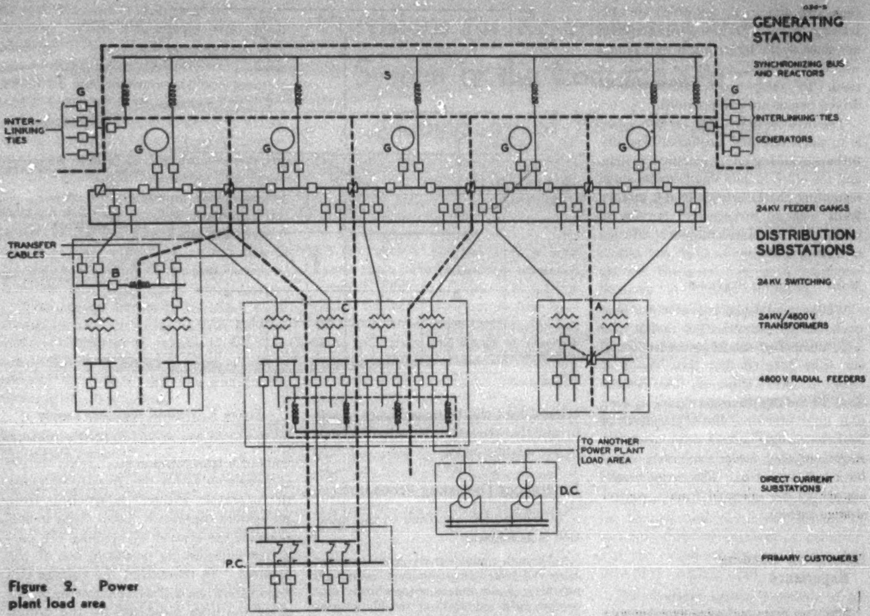

Figure 2. Power plant load area

metal clad and each phase segregated in its own metal enclosure.

In the load area are three kinds of substations. One kind (*B*) has 24-kv switching and usually serves not only as a "satellite center" for the collecting of large industrial and small substation loads, but also as a transferable load to aid in adjusting the size of the load area. Each of its bus sections is separated in a manner similar to the generating-station switch house. Substations of this kind are costly to build and to man but fortunately not many of them are required.

A second kind (*C*) is that commonly used to supply heavy industrial and commercial areas. Such a substation has no 24-kv switching. Its transformers are connected together on their 4.8-kv side by a star-connected synchronizing bus with its reactors which is carefully segregated from the other busses and equipment. The switchgear for each transformer and its "feeder gangs" is also segregated from its neighbors.

A third kind (*A*) is that having no 24-kv switching and no 4.8-kv synchronizing bus or reactors. Each transformer serves a "gang" of 4.8-kv feeders and is so arranged that, should a transformer or the 24-kv cable feeding it fail, its "gang" of feeders will be automatically thrown onto the spare transformer capacity with an outage of some two seconds.

A fourth type (D.C.) is the d-c substation, each of which is fed from at least two separate power-plant load areas and often from three, so that the loss of any power-plant load area will not cripple any d-c substation. Should there be a complete shutdown of all the power areas feeding the d-c system, the d-c load will be picked up by motor generator sets which are equipped with load-limiting apparatus for that purpose.

A fifth type is the a-c network in the downtown area. These are not shown on figure 2. We do not contemplate that any of these networks as laid out is likely to exceed 10,000-kw load. Each is normally fed at 4.8 kv from a substation in one power-plant load area and arranged to be transferred to a substation fed from another power-plant area should the first one fail. The quantities of load involved are not sufficient to present any problem in picking them up.

A sixth type is the primary customer installation (P.C.). Care is taken to see that each feed to such a customer is served from a separate section of supply substation or from separate substations.

In figure 3 there is shown the methods of serving a load area by overhead 120-kv transmission lines. Here the segregation of trouble is not quite so complete but each 120-kv bus section is separately relayed to localize trouble. Also, each 24-kv bus section is carefully segregated by steel barrier walls and double section switches and the 24-kv lines to distribution substations are spread over the bus sections in the same manner as described for the typical power-plant load area. While we have not shown them, the distribution substations are of the same type as shown in figure 2. Again, the dotted lines show the zones of segregation.

From the above description, it is evident that there is no fundamental obstacle to the starting of such a system from a complete shutdown because the load can be picked up in small enough pieces to be well within safe limits for generators and boiler plant.

Auxiliary Supply

Generating Plants

▌It is the practice of the company in each of its generating plants to provide completely independent steam-turbine-driven d-c generators to supply most of those essential auxiliaries which are electrically driven. The principal exceptions are some of the larger boiler feed pumps where system-fed a-c motor drives are used. In these cases, steam-turbine-driven pumps are also provided.

The reasons for so doing are two. One is to shield essential auxiliaries from disturbances arising on the electrical system, and the other to gain the desirable speed regulating characteristics of d-c motors. With such an arrangement, service to power-plant auxiliaries will not be affected by system shutdowns.

MAIN SWITCHING STATIONS

While no particular provision has been made for the simultaneous closing of a large number of the 24-kv feeder breakers, it is believed that three could be closed at once. However, there is little need for the simultaneous closing of even that many since the size of the pieces of load can readily be kept down to what a single outgoing feeder can safely carry for a half hour or so. The circuit breakers are all d-c operated from a control storage battery.

Emergency Loading Experience

While we have had some experience in the matter of suddenly applied overload on generators, most of that experience occurred some years ago before particular interest in that aspect of the problem had been aroused and the records and our memories are not too specific. However, there is a partial record of one case in which a group of generators were suddenly loaded from 80 per cent to about 125 per cent of rating without change of field excitation. The voltage dropped to about 80 per cent of normal and the frequency to 58 cycles, but no generator dropped its load. The short-circuit ratio of these generators probably varied from 0.9 to 1.6, the latter being for the older vertical Curtis turbine then in use. The record contains no statement as to the change in character of the load with that change of voltage and frequency. This case is cited for what it may be worth, recognizing its limitations.

No field tests have been made to determine the change in system load with variation of the voltage or frequency.

The proportion of the load of an area which will immediately be picked up on restoration of service will, of course, vary with the character of the area load. For The Detroit Edison Company system, which is heavily industrial, experience has shown that 40 to 60 per cent of the original load will be immediately picked up and that the remainder will come back in five minutes or so.

Emergency Operating Procedure

In general, the approach to this question is as follows:

1. Through equipment segregation and by relay and switchgear equipment, means are provided to disconnect automatically and confine most any form of trouble we can foresee.

2. If, for any reason, the several lines of defense provided by the above shall have successively failed and the fault becomes uncontrollable, it is desirable that the operators *immediately* supplement the protective equipment by whatever action is necessary to localize and clear the fault, bearing in mind that the first concern is for the safety of the system as a whole and thereafter for the particular load area or substation, as the case may be. To guide them in so doing, standard emergency switching instructions have been developed. These instructions are designed to be carried out on the initiative of the power plant and substation operators without recourse to the system supervisors wherever that is practicable—and it usually is.

3. If, despite, the automatic protective gear and the action of operators, the system or any of its load areas goes completely dead, the central system supervisors will take control, since the moves necessary to restore service will probably extend outside the ken of any one group of operators.

Because the action necessary to restore service may vary so widely and because of the broad experience and good judgment of the central system supervisors, we have not so far attempted any specific emergency instructions for their guidance.

Perhaps the best way to illustrate the effect of this approach is to outline the procedure followed in emergencies.

When the equivalent of lamp voltage falls to 80 volts at a power plant or 70 volts at a transmission step-down station and remains so for one minute or more, the operator, without instruction from the system supervisor, takes steps to sectionalize the system by opening the particular interlinking points in use at the moment. If, thereafter, the voltage still remains low, he will sectionalize his busses along the lines indicated by the dotted lines in figures 2 or 3, as the case may be, beginning with whichever section he thinks most likely to be in trouble. As soon as the faulted section is cleared, the operator calls the system supervisor and reports the situation.

It is interesting to note that the index upon which the necessity for emergency switching turns is the voltmeter reading. It has been found from experience that, under fault conditions, the behavior of current-indicating devices is often so erratic as to make them undependable and that persisting low voltage is about the only reliable criterion.

Suppose, now, that the trouble has been so serious that an entire plant and its load area is down and that the situation has been referred to the central system supervisors. The first step would probably be to survey the switchgear and busses to determine what bus sections were in condition to go back into service. Following this, all outgoing lines would probably be opened. Thereafter, the running generators would be brought up to speed, one at a time, connected to a considerable section of bus, and loaded by closing the outgoing feeders one at a time. The generators would be synchronized with the synchronizing bus if it were in commission. If not, they would be synchronized to their neighboring generators. When everything was again running, if the synchronizing bus were out of commission, the generator busses might be sectionalized into two parts, if need be, to minimize short-circuit duty.

There is only one precaution to be observed in closing the outgoing feeders and that applies to the feeders running to the industrial substations (*C* in figure 2). These feeders, being tied together through a 4.8-kv synchronizing bus, the system supervisor might find it necessary to open these synchronizing bus ties to prevent overloading of the first feeders to be closed in. This can readily be done.

With respect to the boiler plant, there should be little difficulty because the load will not be picked up in large pieces. An ample supply of make-up water is held in reserve to replace any loss due to the blowing of safety valves.

It is not necessary to alter any relay settings, either at the power plants or at the substations.

To guard against a failure of communication facilities, the company has built up a private telephone system connecting the system supervisors with each generating plant and each principal substation. This is supplemented by Bell System phones. In the case of the Trenton Channel and Marysville power plants, which are more remote from the system supervisors, there is also provided carrier-current communication. There is, in addition, radio telegraph to the Marysville plant. Very rarely have we had to use either the carrier-current or the radiotelegraphic communication. The chance of a simultaneous failure of these communication facilities is very small but, if that contingency did arise and the operators could not communicate with the central system supervisors, they are instructed to proceed to restore service within their own area or substation on their own initiative.

While the power plant and substation operators are required to become very familiar with operating instructions affecting restoration of service, no specific rehearsals have been conducted. It is felt that any of the instructions are so much in line with the steps which would normally be taken by an experienced operator as to preclude the necessity of staged rehearsals.

Discussion

Discussion will be found in the 1940 annual Transactions volume and in the 1940 "Transactions Supplement" to Electrical Engineering.

Provisions for Re-energizing the Electric System of the Consolidated Edison Company of New York, Inc.

G. R. MILNE
MEMBER AIEE

H. C. OTTEN
MEMBER AIEE

In the course of the last three or four years there have been a few instances in which generating stations supplying electric service in large metropolitan systems have shut down temporarily because of storms and floods of unusual severity or because of accidents resulting in fires which could not be quickly brought under control. These occurrences, while fortunately very infrequent, have focussed attention upon the problem of starting up a large system in the event of a complete shutdown of one or more generating stations supplying it. It is therefore the purpose of this paper to present:

1. Some of the more important considerations affecting the design of the distribution system and the generating stations in the Consolidated Edison system with respect to the ability to restore service after a complete shutdown.

2. The principal features of the operations involved in re-energizing the electric system, in accordance with a predetermined plan.

3. A review of some operating experiences related to the problem of re-energizing the system.

Description of the System

The Consolidated Edison system furnishes electric service to all of Greater New York City, with the exception of the borough of Richmond and a small portion of the borough of Queens. It also supplies nearly all of Westchester County.

Approximately 2,400,000 consumers are served in an area of about 700 square miles having a total population of nearly 8,000,000.

The electrical supply is derived principally from 11 steam generating stations located within the territory served and having a total installed capacity of 2,556,000 kilowatts. About 70 per cent of the generating capacity operates at 60 cycles and the remainder at 25 cycles.

All of the generating stations are interconnected by direct tie feeders for each of the two frequencies and by five frequency changers having a combined capacity of 190,000 kilowatts. This system normally operates in parallel with the system of the Niagara-Hudson Corporation through a 60-cycle connection of 200,000-kva capacity and with the system of the Brooklyn-Manhattan Transit Corporation through a 25-cycle connection of 40,000-kva capacity.

Figure 1 is an outline map of the territory served showing the location of each generating station.

Figure 2 is a single-line diagram showing the connections between generating stations, their net generating capacity, and the estimated district loads at the time of the peak in 1939.

The 60-cycle system supplies, in all parts of the territory served, residential, general commercial, and industrial loads as well as the entire load of the municipal rapid-transit system. The 60-cycle load at the time of the system peak represents about 70 per cent of the total load.

The 25-cycle system supplies a large d-c traction load which includes the terminal divisions of all of the trunk-line railroads entering New York City; a large d-c load for residential and commercial use, mostly in the borough of Manhattan; a small amount of a-c commercial load, and some single-phase a-c traction load.

The total system load at the time of the peak in 1939 was 1,704,000 kilowatts. The energy distributed during that year was slightly over $7^{1}/_{4}$ billion kilowatthours.

Paper 40-33, recommended by the AIEE committee on power generation, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 24, 1939; made available for preprinting December 16, 1939; released for final publication March 30, 1940.

G. R. Milne is outside plant engineer, and H. C. Otten is assistant manager in the system operation department, Consolidated Edison Company of New York, Inc., New York.

The authors wish to express their appreciation of the advice and assistance rendered by W. E. Caldwell, mechanical plant engineer of the Consolidated Edison Company, in the preparation of this paper.

Fundamental Considerations Affecting the Design of the Distribution System and the Generating Stations

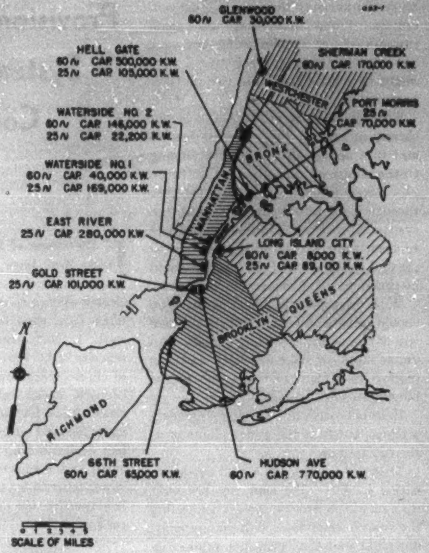

Figure 1. Territory supplied by the Consolidated Edison system and the locations of the generating stations

Electric distribution systems and their sources of supply are designed so as to provide electric service of the highest quality that the density and character of the load will justify. Probably the most important measure of this quality is that the service shall be substantially free from interruption. However, equally important from a system standpoint, is the ability to restore service quickly after an interruption may occur and with little or no damage to equipment during the shutting down or re-energizing periods. In suburban and rural areas the radial type of electric distribution provides service which is rarely interrupted and at a cost sufficiently low so as to be commercially practical. With such a system the load is divided into units which are small in relation to the capacity of the sources of supply and the switching of these units is directly under the control of the local operating personnel. The procedure to be followed in restoring service to a radial system consists of reconnecting to the substations and generating source only such load as those stations and the associated feeders can safely carry. Furthermore, the radial distribution feeders are practically self-protecting in that the feeders and associated load are simultaneously interrupted and therefore do not suffer damage during system shutdown.

To provide the high degree of service continuity required in metropolitan areas, the multiple-feed low-voltage network was developed. This form of distribution has been used continuously since the establishment of d-c service from the Edison system in New York in 1882. The development of the a-c network protector led to the application of the same principle to a-c distribution in Manhattan in 1922. Operating experience including the operating record of cable limiters has demonstrated the high degree of reliability of the low-voltage network and that the over-all service reliability is dependent almost entirely on the reliability of the sources which supply the network. It is not economical or reasonable to provide for the maintenance of continuous service throughout every conceivable contingency condition nor for contingencies having a frequency probability so low that they can be disregarded. Furthermore, not every contingency of nature can be foreseen. It is essential therefore that means be provided for re-energizing individual networks or a system comprising a number of networks.

The system plan adopted by the Consolidated Edison Company contemplates that the generating stations will be interconnected normally by a system of direct tie feeders and frequency changers only and that the total distribution load will be segregated into blocks, which, even at peak-load conditions, are small by comparison with the capacity of the interconnected stations. The existing area segregations are shown in figure 3.

While network areas should be small for facility in restarting after shutdown they should not be made too small as the distribution layout thereby becomes relatively expensive. For a system as extensive as that in New York, we believe that each a-c network should be supplied by from 8 to 12 high-voltage feeders. In order to load these feeders, consisting of three-conductor 800,000-circular-mil cable at 13 kv and three-conductor 500,000-circular-mil cable at 27 kv to reasonable values, it follows that networks supplied by feeders at the lower voltage should range in capacity from 50 to 75 megawatts, and from 75 to 150 megawatts if supplied at the higher distribution voltage. Not all of the areas supplied from a given station need be kept to the minimum values as a station should be able to restart progressively larger units as re-energizing proceeds. If some areas are too large they cannot be selected for initial restarting. In the absence of extensive experience in restarting networks, the above values of area load ranging from five to ten per cent of the system peak load are largely based on opinion but are believed to be conservative. Moreover the limitation of an a-c network to a size appropriate for supply derived from 12 feeders makes it necessary to operate simultaneously only a moderate number of circuit breakers at the instant of restarting.

When the load in a segregated a-c network approaches the above values, the network is subdivided and in some instances regrouped to form other segregated networks whose physical boundaries and primary feeder rearrangements have been previously planned and partially installed in advance of the load growth.

Each primary feeder to a segregated a-c network should supply load in only that one area. If this requirement is not observed, it would be impossible to energize one network without energizing equipment in other networks at the same time. This would either mean starting a number of networks simultaneously; damage to equipment in other networks not being energized; or delaying the starting up until the slow process of blocking open protectors in conflicting areas can be completed. A network to be suitable for independent restarting must be segregated both primary and secondary from other networks.

All of the primary feeders to a given a-c network area should, in our opinion, derive their supply from the electrical galleries of one generating station. During unusual operations such as the restoration of service after shutdown, such an arrangement minimizes the amount of operating co-ordination required and thereby simplifies the operating rules covering the re-energizing procedure. Furthermore, in the event that communication between stations or the direct tie feeders interconnecting them are interrupted such a plan enables a station to operate as an independent unit usually able to supply the load of the area it serves.

Since the 60-cycle load in an entire area is to be supplied from one station under this plan it follows that electrical and mechanical segregation should be provided to such a degree as to protect the continuity of service during reasonable contingencies. Thus the main bus should be divided into a number of major sections, each separated by gas-tight fire walls so that trouble in one section will not physically communicate to another. Electrical ties between major bus sections which are normally alive should connect through the fire walls by indirect paths such as a synchronizing bus and there should be a minimum of two sets of independent switching and protective gear between a section on which a fault is assumed to occur and other sections. One set of protective gear between a common synchronizing bus and each load bus would seem sufficient on the assumption that not more than one set of protective gear will fail to function properly during a given fault.

The primary feeders to each a-c network should be divided among the major sections and sufficient network transformer and mains cable capacity should be installed so that in emergency the peak load can be carried or re-energized after shutdown with one major bus section out of service.

The number of major segregations provided at the station should be such that the lowest over-all system costs result. The less the number of major sections provided in the station, the greater is the percentage of reserve equipment capacity on the network system required for operation with one section out. Experience indicates that a station can be economically limited to two major sections only when the a-c networks supplied from it are small and in the early stages of development. With networks of moderate or large size at least three and probably four major sections are economical.

Each major section may be divided into two or more subsections further to promote reliability in which case differential protection or its equivalent should be provided on each section.

The d-c control supply and the control wiring in the 60-cycle generating stations must be adequate to permit the simultaneous closing of the requisite number of circuit breakers for restarting a network. The relaying must be such that the feeders will not trip out at the moment of re-energizing due to the current surge.

In the foregoing paragraphs the more significant design features of the a-c network distribution system in New York have been mentioned. While many of these features are considered applicable to d-c network distribution, the development of the much older d-c system progressed along different lines.

D-c network distribution is confined to an area of about 19 square miles in the borough of Manhattan. There is also a very small amount of d-c load in Brooklyn. The Manhattan d-c network is not divided into segregated areas but con-

sists of a continuous grid supplied from 41 d-c substations over approximately 2,400 low-voltage feeders. Cable limiters are installed in all d-c mains at the boundaries of zones supplied by the d-c feeders from adjacent substations.

Each of the d-c feeders is connected to the network mains through an automatic air circuit breaker installed in a junction box. These breakers are closed manually but will trip automatically in the event of a feeder fault when the arc causes the breakdown of insulation on a lightly insulated control wire embedded in the outer layer of strands of the feeder cable.

It is expected that in the event of a total interruption of d-c supply from a given substation the limiters will blow if the current flowing to the affected area over the mains cables reaches sufficiently high values to cause severe cable damage unless interrupted. Sufficient experience has been obtained with cable-limiter operation during faults on mains cable to indicate that the limiters are effective in preventing widespread damage to low-voltage mains cable during fault conditions.

Re-energizing the d-c network in the event of a complete shutdown requires that a selected group of about six low-voltage feeders from each of more than 25 substations be re-energized simultaneously and that the remaining d-c feeders from all 41 substations be cut in as rapidly thereafter as practicable. The operations required for starting the large number of converters upon restoration of 25-cycle supply; connection of these converters to an isolated d-c bus in each substation; connection of the dead feeders selected for initial re-energizing to another isolated bus and particularly the operation of tying these two isolated busses together in the selected substations at the same instant require very close co-ordination for which a special emergency telegraph signaling system has been provided.

Responsibility for Co-ordination and Execution of Operations in Re-energizing the System

Responsibility for co-ordinating operations in the electric system of the company is assigned to the system and district operators.

It is the system operator's responsibility to direct the operation of production facilities so as to maintain sufficient generator, tie feeder, and frequency-changer capacity in service to meet the requirements of the load connected to each generating-station bus. In the event that one or more generating stations are shut down and are ready to resume operation, the system operator is responsible for determining the order in which these stations or reserve stations are to be started up. He will order the re-energizing of busses, reconnection of tie feeders and frequency changers, and will determine in conjunction with the district operators the order in which the segregated loads are to be re-energized to utilize capacity to the best advantage as it is made available.

The district operators in each of the three districts established for convenience in administration are responsible for the direction of distribution operations in their respective districts. It is their responsibility to direct the switching operations in the field and in the stations which are required to re-energize each load area as capacity is made available after shutdown.

The generating station operators and substation operators are responsible for disconnecting all feeders, generators, and frequency changers in the event of the complete shutdown of a given station. They also are required to perform, on their own initiative, specified preliminary operations to prepare for re-energizing the system.

While it is expected that in any emergency involving the shutdown of one or more generating stations, the operations performed in restoring service would be co-ordinated by the system operator and district operators in the manner previously described, it is recognized that a concurrent failure of communication facilities might make it imperative for the switchboard operator at the generating station to assume the initiative in restoring part or all of the load as soon as the station is prepared to do so. The distribution system is designed to facilitate re-energizing in this manner. Several proposals are being investigated in an effort to develop a standard procedure which the individual generating station operators could follow in the event that communication is interrupted and it is necessary to restore the direct tie feeders in order to obtain assistance from an adjacent station when re-energizing blocks of network load.

Written instructions covering the procedure to be followed by the generating station and substation operating personnel in the event of a complete shutdown of any station are revised and reissued as often as required by changes in system facilities.

In determining the form and contents of the instructions simplicity and conciseness were emphasized so that they can be used for quick reference when necessary, and to encourage frequent review by the individuals concerned and thereby to promote their familiarity with prescribed procedure. It is recognized that it is impractical to prepare, in advance, complete and specific instructions to apply to a very large number of assumed emergency conditions. The instructions for re-energizing the system are therefore written to cover selected cases including:

1. The shutdown of each 60-cycle generating station separately.
2. The shutdown of all 60-cycle generating stations.
3. The shutdown of the entire d-c network in Manhattan and the associated 25-cycle system.

Procedure for Re-energizing the System

It is assumed, for the purpose of this discussion, that the entire electrical system of the Consolidated Edison Company has been shut down, that the generating stations are in a cold condition, that the electrical ties with other utility systems such as the Niagara Hudson Corporation and the Brooklyn-Manhattan Transit Corporation are open, that all distribution feeder load has been disconnected and that all generators, frequency changers, and tie feeders have been disconnected. This represents the most difficult condition to be met from the standpoint of complexity of the operations required to start up the system.

In the extreme condition where no power is assumed to be available from other utility systems it would be necessary to establish a supply of electrical energy sufficient to meet the initial requirements of electrically driven auxiliaries. If the tie feeders between generating stations are available auxiliary power can be made available to all stations by starting one main 60-cycle or 25-cycle unit in any one of several stations. The Hell Gate and Hudson Avenue stations have house turbine-generator sets which can be started on steam generated by natural draft in the stoker-fired boilers. These generators can provide sufficient auxiliary power for operation of at least two of the main turbogenerators ranging in size from 35,000 kw to 50,000 kw in either station. If a 25-cycle turbogenerator in a station having steam-driven auxiliaries is selected for initial starting, it can be used to energize the 25-cycle busses in all stations and the 35,000-kw frequency changer at Hell Gate station may be started and used to energize the 60-cycle busses in all stations.

With the main 60-cycle busses and 25-cycle busses energized and a supply of auxiliary power available in all stations the next step would be to start and synchronize the remaining frequency changers so as to complete the restoration of all interconnections among the generating stations in the Consolidated Edison system.

In order to provide load for the turbogenerators as they are successively started and synchronized and to build up the fires in the boilers it would be necessary at this point to begin re-energizing 25-cycle and 60-cycle feeders supplying radial load only. This would permit adding load in convenient amounts and would fully restore the large traction load supplied from the 25-cycle system, restore all of the 60-cycle load in Westchester County, and partially restore 60-cycle radial load in the outlying areas in the boroughs of Bronx and Brooklyn. At the time of the system peak in 1939 the total amount of radial load thus restored would be approximately 260,000 kilowatts or about 15 per cent of the total system load.

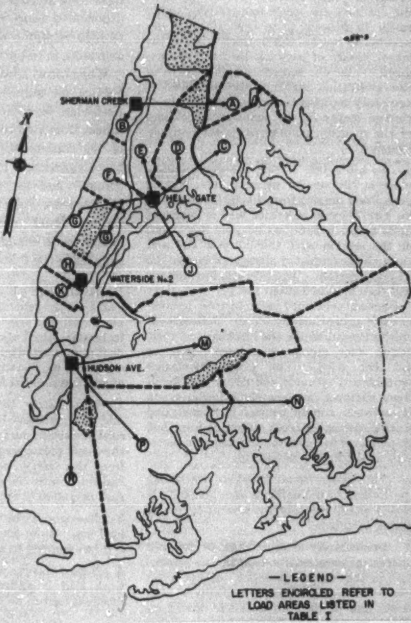

Figure 3. Segregated 60-cycle load areas in New York City

With this amount of load divided among the generating stations it would be possible to restore the 60-cycle networks to service, beginning with the areas having the smallest load and finishing with the largest networks, in each case using the method of restoration to be described later in this paper.

After all of the 60-cycle networks have been restored it would be possible to restore additional 60-cycle radial load amounting to over 200,000 kw which is supplied from feeders which also supply the network load or which is dependent upon the re-energizing of the network load itself. An important 60-cycle load is that of the municipal rapid-transit system in which most of the conversion units are rectifiers and require a supply of auxiliary power from the network before the traction load can be restored. Normal train movements are dependent upon supply from the network for track signals.

The restoration of substantially normal supply to the 60-cycle radial and network loads and to the 25-cycle radial load would build up the total load on the interconnected generating stations to the point where the boiler steaming rates should be high enough to permit the addition of the large block of load represented by the d-c network in Manhattan as the final step in restoring normal service. At the time of the system peak the load on this network is about 375,000 kilowatts and represents about 28 per cent of the total load in the remainder of the system.

The general method of re-energizing each of the 60-cycle networks may be summarized briefly as follows:

1. After the generating station busses have been re-energized, the direct tie feeders between generating stations have been restored, and the frequency changers synchronized, at least one turbogenerator is synchronized to the bus in each station.

2. While additional generators are being started, small blocks of radial 25- and 60-cycle load are connected successively to the busses in each station by re-energizing individual radial feeders as rapidly as consistent with the increase in capacity as the available boiler output is increased. This process is continued until all of the available load has been re-energized except that which would require special switching operations in the field to separate it from network load in the case of feeders supplying both kinds of load.

3. The overcurrent protective relays on all of the 60-cycle tie feeders between generating stations are made inoperative temporarily to prevent them from tripping unnecessarily on the surges which occur as the larger blocks of network load are re-energized. The d-c control supply feeders in the generating stations are paralleled if necessary to insure an adequate supply of control energy for the simultaneous closure of the requisite number of network supply feeders.

4. In a 60-cycle station supplying one or more of the smaller network areas having peak loads ranging from 40,000 kw to 80,000 kw the 60-cycle generator load is increased until as much power as possible is sent out of the station over the 60-cycle ties and through the frequency changer, if any, to the 25-cycle system. The 60-cycle bus voltage will then be raised about five per cent above the normal scheduled value in order to compensate approximately for the increased excitation required for the block of load to be added since automatic voltage regulators are not used. The generating-station switchboard operator will notify the boiler-room engineer immediately before a group of network supply feeders is re-energized so that the boiler room operating force will be prepared to make any adjustments necessary as the load is picked up.

5. The feeder circuit breakers controlling the feeders to the network area selected are closed simultaneously by several operators acting in unison.

6. Immediately after a block of network load is re-energized the load on the generators in the station at which the operation was performed is adjusted manually so that about half of the load added is carried on these generators and the remainder is carried on the generators in other parts of the system through the ties and frequency changers. The bus voltage is adjusted to the normal scheduled value after a block of network load is added unless the same station is to prepare for the immediate addition of another block of load.

This method of re-energizing a typical block of network load is based upon the assumption that the entire Consolidated Edison electric system has been shut down and is to be re-energized with all stations and substantially all parts of the distribution system intact and available for service. In any actual case of shutdown it is unlikely that more than one station will be seriously affected. It is possible, however, that the affected station will have to be restored to service and its load re-energized while one or more of the bus sections are damaged, or while one or more of the main turbogenerators is unavailable for service. All such situations present special problems which require slight changes in the general plan presented.

One of the most important deviations from the general plan would be encountered in the case where a generating station having adequate generating capacity available to carry the normal load might have to be started from a shut-down condition at a time when the 60-cycle ties to other stations were not available for assistance in re-energizing the networks.

While this is a rather remote possibility because the number of separate 60-cycle tie feeders to adjacent stations provided ranges from two to nine and all but one of the stations supplying network load has a connection to the 25-cycle system through one or two large frequency changers we believe that the isolated station would have no particular difficulty in re-energizing the networks it supplies in the following manner:

1. Re-energize all of the available radial load as in the general case and, if necessary, block open the relatively few network protectors at distribution banks connected to dual-purpose feeders which can then be re-energized to restore substantial amounts of additional radial load.

2. Immediately before re-energizing the first and smallest block of network load raise the steam output from the boilers and the steam pressure until steam is discharged from the safety valves. The supply of make-up water is normally adequate for such operation in any of the stations.

3. Re-energize the first block of network load and restore steam pressure to normal if it has dropped to a point below normal.

4. Repeat this process as each block of network load is added, leaving the largest blocks of load to be re-energized last.

Under some conditions it would be feasible to restore service to all or nearly all of the 60-cycle load supplied from a generating station while all of the generators were temporarily unavailable for service because of some condition affecting all of the essential auxiliaries. Such a condition occurred in one instance under circumstances outlined below.

Operating Experiences

The only actual experience obtained in re-energizing segregated 60-cycle load areas in the Consolidated Edison system was on the occasion of the shutdown of the Hell Gate generating station on September 21, 1938, shortly after the work was completed in segregating the load areas supplied by this station. This shutdown was the result of a tidal flood accompanying a hurricane which passed close to New York City on that date. The re-energizing of the areas affected was successfully carried out by following as closely as practicable the methods outlined above. The salient features of this experience were:

1. The shutdown of all 25-cycle and 60-cycle generators in the station was forced by loss of steam pressure following the partial or complete submersion of nearly all of the essential auxiliaries and the complete interruption of the power supply for the auxiliaries which are electrically driven.

2. The 11-kv 25-cycle busses, 13-kv 60-cycle busses, and the associated switchgear were not damaged although all supply to the 60-cycle busses was interrupted because of overloads on the tie feeders and the frequency changer.

3. The shutdown occurred about $1^{3}/_{4}$ hours after the time of the system load peak for the day at which time the system load normally is declining at a rate of approximately ten per cent per hour.

4. All 60-cycle service in the north half of the borough of Manhattan and all service in the borough of Bronx and county of Westchester were interrupted. This load amounted to about 260,000 kilowatts.

5. About one-quarter of the interrupted load was restored within six minutes. Service in the remainder of the affected area was restored in several stages over a period of $5^{3}/_{4}$ hours. Since none of the generators at Hell Gate station was available for operation for several days after the shutdown, 60-cycle power obtained principally from the Niagara-Hudson system was utilized in restoring service.

6. No difficulty was experienced in re-energizing the networks. The largest block of load re-energized in one operation was 90,000 kilowatts which included all of the load in Westchester County and a small section in New York City. This load was re-energized six minutes after it was interrupted and the load picked up was about equal to the load dropped. The next largest block of load was that of one of the networks in Manhattan. This network was re-energized 41 minutes after the interruption occurred and increased the load on the Niagara-Hudson tie by 30,000 kilowatts which was almost exactly the amount of load in the area at the time of the interruption. A few minutes later another of the Manhattan networks was re-energized but the load increment was only 28,000 kilowatts, about 30 per cent less than the load in that area at the time of the interruption. This reduction of load was partly accounted for by the fact that the service voltage in the areas restored was from 8 to 18 per cent below normal immediately after the second block of network load was added. Seven minutes later, after excitation had been adjusted in the Niagara-Hudson system, the service voltage in the re-energized areas was sufficiently improved to permit re-energizing a third block of network load in New York City with the same effect on load and volt-

age as before. The remaining networks were re-energized shortly thereafter with increased 60-cycle power supply available from other generating stations in New York City over tie feeders which could not be restored earlier because of a system ground fault condition requiring several hours to localize and eliminate.

7. It was found entirely practical to close from 6 to 11 feeder breakers at the generating station in such a manner as to re-energize each network without causing network protector fuses to blow because of temporary local overloads. In the case where 11 breakers had to be closed they were closed in two groups of 6 and 5 respectively by several operators working together.

On the occasion of the shutdown of Hell Gate station the circumstances were such that no experience was obtained in re-energizing large blocks of load with power supplied principally by the generators in the station affected.

However, an indication of the probable effect of re-energizing a large block of load from a given generating station, under conditions where the interconnections among all of the generating stations are operating normally, may be obtained from actual experience in several cases where automatic tripping of transmission-line breakers in the Niagara-Hudson system have resulted in instantaneous increases of 100 to 150 megawatts in the load on the Consolidated Edison system.

In all cases the increased load has been picked up by the interconnected stations in New York with slight effect on the system frequency and voltage.

The largest of these instantaneously applied loads on record occurred at a time when the Consolidated Edison system was receiving 150 megawatts from the Niagara-Hudson system and a bus fault in a substation located near the boundary between the two system territories caused the transmission lines to open at that point. At that time the total generator load in the Consolidated Edison system was 789 megawatts of which about 60 per cent was 60-cycle generation. The instantaneous load increase of 150 megawatts was imposed upon the system through connections to the 60-cycle busses in the Hell Gate and Sherman Creek stations but was shared by all of the interconnected stations with a momentary decrease in frequency of one-half cycle and a voltage dip of from $2^1/_2$ to 9 per cent in various parts of the system. The system frequency was restored to normal within three minutes. Unfortunately there is no complete record of the magnitude of the load increase at each of the generating stations. None of the tie feeders or frequency changers tripped out.

In this case the sudden increment of load represented 19 per cent of the previous load on all generators, 32 per cent of the load on the 60-cycle generators alone, 11 per cent of the total running generator capacity, 79 per cent of the running frequency-changer capacity, and approximately 11 per cent of the total net hot boiler capacity.

The boiler equipment in these stations includes a wide variety of types among which are stoker-fired boilers with and without automatic combustion control and pulverized-fuel installations of the unit-mill type and of the bin type.

The operating experiences mentioned indicate that no particular difficulty should be encountered in re-energizing the largest blocks of network load contemplated under the present design objectives provided that substantially normal tie-feeder and frequency-changer capacity is available for service at the time.

Discussion

Discussion will be found in the 1940 annual Transactions volume and in the 1940 "Transactions Supplement" to Electrical Engineering.

The Co-ordination of Electrical Equipment With Basic Insulation Levels

J. H. FOOTE
FELLOW AIEE

J. R. NORTH
MEMBER AIEE

Basic insulation levels have been defined, and a list of proposed values has been determined by national committees charged with this responsibility. The purpose of this paper is to discuss some of the principles useful in selecting electrical equipment conforming to the requirements of that basic insulation level necessary to assure satisfactory service while operating within the voltage range and under the system conditions expected.

Since the lowest-allowable basic insulation level is closely associated with the protected level provided by the surge-limiting or surge protective equipment, and since the rating of protective equipment selected is closely associated with values of system operating voltage to ground, it is evident that there exist interrelations among:

A. Voltages expected to exist on the electrical system

(*a*). Low frequency or dynamic

(*b*). Surge

B. Voltages permitted by surge protective devices

C. Basic insulation levels

D. Insulation strengths of electrical equipment

The latest proposed values for basic insulation levels are being reported to the Institute by representatives of the national committees having these matters in hand.[1] The performance of lightning-surge protective devices and other related matters also are being presented in associated papers before the Institute.[2,3]

Operating Requirements of Apparatus Insulation

It is of interest to examine the relations existing between required insulation strengths and service conditions on operating systems. Apparatus must be designed to withstand satisfactorily a variety of voltages imposed upon it. Such voltages include:

A. Continuously applied low-frequency voltage

(*a*). Between terminals

(*b*). Between live parts and ground

B. Occasionally applied low-frequency overvoltages

(*a*). Between terminals

(*b*). Between live parts and ground

C. Occasionally applied inpulse overvoltages between live parts and ground

The basic insulation level as now de-

Paper 40-35, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE winter convention, New York, N. Y., January 22-26, 1940. Manuscript submitted November 17, 1939; made available for preprinting December 28, 1939; released for final publication March 27, 1940.

J. H. Foote is supervising engineer and J. R. North is assistant electrical engineer, The Commonwealth and Southern Corporation, Jackson, Mich.

Acknowledgment is made of the valuable assistance rendered by M. C. Westrate in the analysis of these insulation-co-ordination problems.

[1] For all numbered references, see list at end of paper.

fined directly refers only to the last of these varieties. A study of the relationships which should exist between this characteristic and the others is essential to the successful co-ordination of the design characteristics of electrical equipment with basic insulation levels. In the past, it has been common practice to relate insulation strengths to the rated continuous low-frequency voltage *between terminals* for which the apparatus was designed. However, a study of the considerations enumerated above leads to the conclusion that insulation strengths more properly should be related both to (*a*) the surge voltages, and (*b*) the continuous dynamic voltages expected to exist *between live parts and ground*.

A fundamental requirement of apparatus insulation is that its strength between live parts and ground shall be at least equal to the maximum voltage expected to occur between live parts and ground. In the case of impulse surges this maximum value may be considered to be the "protected level" provided by the associated protective apparatus. Therefore, that basic insulation level which is equal to or in excess of the established "protected level" would be the minimum insulation level applicable to the apparatus in question.

As discussed rather completely in a former paper,[4] the protected level must be placed sufficiently above the expected performance of the protective device to provide a reasonable margin which will insure the integrity of the protected level. This margin must take into account many factors, including manufacturing tolerances, layout and arrangement of the station, vagaries of surges and protective equipment, assurance of selective operation of the protective device, etc.

Basic Insulation Levels

The present accepted definition of "basic insulation levels" is as follows:

> "Basic impulse insulation levels are reference levels expressed in impulse crest voltage with a standard wave not longer than a $1^1/_2$x40-microsecond wave. Apparatus insulation as demonstrated by suitable tests shall be equal to or greater than the basic insulation level."

For many years, insulation levels have been defined, perhaps inadequately, in terms of test voltages impressed for a period of time at low frequencies. The basic insulation levels under discussion, however, are defined in terms of impulse voltages with no mention of low-frequency or sustained-voltage strengths. The definition contemplates that apparatus shall withstand successfully the imposition of surges having values as great as the basic insulation level for which the apparatus was designed.

Table I. Typical 4,160-Volt Wye Substation

Insulation Design Basis: Basic Insulation Level 60 on Bus and Important Apparatus; 45 Elsewhere

Item	Apparatus Insulation Classification* (Kv)	Voltage Rating* (Kv)	Withstand Voltage

* This designation is that at present used by manufacturers.

† Lowest standard rating.

** Flashover rating. Impulse withstand test not yet determined.

The basic-impulse-insulation-level values most recently proposed, as given in the joint committee report, "Basic Insulation Levels"[1] by Messrs. Powel and Sporn, are as follows:

Proposed Basic Insulation Levels, Impulse Crest Kilovolts

30	150	650
45	200	750
60	250	900
75	350	1,050
95	450	1,300
110	550	1,550

This list of values constitutes a schedule of insulation impulse strengths to ground which may be made available in apparatus of voltage ratings as required by the trade. It is of interest to examine the relationships existing between service conditions on operating systems and the corresponding insulation levels required for apparatus.

Procedure for Selection of a Particular Basic Insulation Level

Since the selection of basic insulation levels is closely associated with the performance of the protective devices which in turn are selected on the basis of maximum dynamic voltages expected to exist at the point of application, the first consideration in selecting a basic insulation level is to determine the maximum operating voltages between conductors. Next, the system connections and the neutral stability must be considered in order to determine the maximum dynamic voltages between conductors and ground under fault conditions. These values lead immediately to the selection of the voltage rating of the protective device, since the low-frequency characteristics of this device must be co-ordinated with the voltages expected to exist between lines and ground. During line-to-ground faults, the voltage on the faulted phase decreases and the voltage between the unfaulted phases and ground generally increases. The magnitude of the voltage between the unfaulted phases and ground will depend upon the system electrical characteristics and the type of fault and will usually exceed the normal line-to-neutral voltage. Under some circumstances, it may exceed the normal line-to-line voltage. The procedure to be followed in calculating these voltages is adequately covered in other papers which have been presented before the Institute and elsewhere.[5,6,7]

Due to the inherent nature of surge protective devices, they have a maximum voltage rating (given in manufacturers' publications and references)[8–12] which is a measure of the maximum dynamic voltage which may be applied to them during fault conditions. There is always a possibility that the protective devices may be surged simultaneously with the fault. Therefore, the maximum voltage between unfaulted phases and ground which can occur at the point of installation is of prime importance in the application of the protective device, and the voltage rating must be determined in conjunction with the type of grounding as well as with the line-to-line system operating voltage.

A study of the characteristics of the protective device under assumed surge conditions, together with provision for a suitable margin, leads immediately to the protected level which will be provided.

Messrs. Sporn and Gross, in their paper, "Rationalization of System Insulation III—Margins Between Basic Insulation Levels and Protected Levels",[3] suggest that a value given by the formula: (0.10× arrester maximum performance)+25 kv, provides a margin which is generally suitable for the conditions usually to be expected. Margins as calculated by this formula are used in the illustrative examples given later in this paper. Engineering consideration of the specific conditions involved may lead to the requirement for different margins in other cases.

For apparatus closely and continuously associated with a protective device, the basic insulation level equal to or just above the protected level thus determined would probably be the minimum to which the apparatus must conform. In certain situations, the importance of service as related to the economics of the application may indicate the wisdom of selecting a higher or lower basic insulation level.

In stations accommodating many connecting lines and in stations of considerable extent, it may be that different types of protective devices are used at different locations; also, the operation of switching equipment may isolate certain apparatus from some of the protective devices. Therefore, it may be that some of the apparatus in the station should be designed to operate with a different protected level and, consequently, a different basic insulation level than other apparatus in the same station.

The impulse characteristics of a particular piece of apparatus and the corresponding characteristics of the protective device must be studied to assure that an adequate margin is being provided between the protected level and the insulation strength of the apparatus at all points on its volt-time curve.

Co-ordination based on insulation levels as determined by full-wave "withstand" voltage tests is satisfactory only when the protected level is relatively flat down to very short time on the volt-time curve.[4] This is practically true for modern lightning arresters where the short-time protected level is determined by the gap breakdown plus suitable tolerance and margin, and the longer-time protected level comparable to the full-wave test on apparatus is determined by the *IR* drop at some specified value of discharge current plus suitable tolerance and margin. If a gap type of protective device such as a protector tube or a plain rod gap is to be used, the protection afforded is based entirely on the time to break down and should not be considered as a level, but rather a volt-time curve. In this case, a comparison of the apparatus chopped-wave impulse-voltage test with the gap breakdown at a comparable time plus suitable tolerance and margin would more accurately represent co-ordination for apparatus on which complete volt-time curves are not available.

In selecting the insulation level for a specific situation, consideration should be given to the requirements as imposed both by the low-frequency voltages and the impulse voltages which may exist. This discussion deals principally with the impulse voltages. However, the low-frequency voltages which may appear on the system must also be given adequate consideration and the low-frequency insulation requirements, both dry and wet, determined with evaluation of specific conditions, such as dirt, condensation, fog, etc. *In the final analysis, the insulation suitable for a given situation will be that which fulfills the low-frequency requirements, the surge-voltage requirements, and the economics involved.*

Illustrative Examples

In order to make more clear and specific the application of this procedure to the selection of impulse levels, three examples are outlined below. It is thought that the conditions selected are those typically existing on many large transmission and distribution systems in the United States. For convenient reference, table IV summarizes the present impulse insulation levels of various types of apparatus listed according to the impulse full-wave voltage-test levels. These data are based on information available at the present time.

EXAMPLE I—TYPICAL LOW-VOLTAGE DISTRIBUTION-SUBSTATION APPARATUS

Assume a 4,160-volt distribution substation with bus and switching equipment indoors, transformers and regulators outdoors, and with overhead lines connected. The supply transformers are all to be connected wye on the low-voltage side with the neutral solidly grounded and delta connected on the high-voltage side. This makes the ratio X_0/X_1 less than one at all times and, therefore, under fault conditions the voltage to ground at the substation will not exceed normal maximum line-to-ground operating voltage[5,6,7] which might be as high as 2,800 volts on the line side of the voltage regulators. This allows the use of 3-kv protective devices for the supply transformers, the bus, or the regulators. Allowing a margin of ten per cent above the arrester maximum performance at 5,000 amperes discharge

Table II. Typical 12,000-Volt Substation

Designed for Basic Insulation Level 95

Item	Apparatus Insulation Classification* (Kv)	Voltage Rating* (Kv)	Withstand Voltage: Low-Frequency Test (Kv RMS)	Withstand Voltage: Impulse Full-Wave Test (Kv Crest)

Bushings: Outdoor	15		45 wet	110

* This designation is that at present used by manufacturers.

** Flashover rating. Impulse withstand test not yet determined.

Available indoor apparatus does not meet basic-insulation-level requirements. Next higher (23 kv) rated breakers are at present available only in ratings 500,000 kva and above.

plus 25 kv and using the "industry characteristics" for a modern 3-kv line-type arrester,[19] the protected level would be 44 kv (17.5+1.7+25=44 kv) and the minimum allowable basic insulation level would thus be 45 kv for apparatus closely connected to the protective devices. However, if the station is large or important, a higher basic insulation level probably is justified for apparatus in the most important locations, and a 60-kv basic insulation level would then be indicated for bus and switch insulators, power transformers, circuit breakers, and other apparatus whose failure would mean a complete station interruption.

The selection of the specific apparatus is next a matter of determining the rating or type designation of each kind of apparatus which will meet the impulse insulation level and the low-frequency requirements as decided upon. Table I illustrates a typical selection of equipment for the 4,160-volt distribution substation of example I as based on present available insulation classes necessary to meet a 60-kv, or 45-kv impulse level where such would be permissible. It will be noted that there is little consistency among the various designations of apparatus insulation classes as related to the impulse full-wave test values for the different types of apparatus. The potential transformers connected to the bus would probably be special, since the present practice is to make 20/1 indoor potential transformers to the 50-kv impulse level. If the potential transformers were connected through an adequately insulated fuse and used only for such purposes that a failure of a potential transformer would not cause an interruption, the 50-kv impulse level probably would be considered satisfactory.

It will be noted that low-frequency test values are also included in table I. As mentioned above, consideration must be given to low-frequency requirements in selecting apparatus. However, further analysis of these requirements is not given here since it is outside the scope of this paper.

EXAMPLE II—TYPICAL HIGH-VOLTAGE DISTRIBUTION-SUBSTATION APPARATUS

Assume a major switching substation including indoor and outdoor apparatus operating at 12,000 volts. The station contains disconnecting switches, oil circuit breakers, voltage regulators, potential and current transformers, and stepdown transformers connected delta. The power supply comes in over several overhead lines, the oil circuit breakers to some of which at times may be operated open and to which potential transformers are connected on the line side in connection with the automatic switching scheme contemplated.

Following the outline of example I, it is determined that the low-frequency line-to-line voltage may reach 13,000. The neutral is not effectively grounded, since the neutral ground is located at the generating station some distance away and the maximum low-frequency line-to-ground voltage is accordingly determined to be 11,000 volts. This will require the use of 12-kv-rated protective devices. With line-type arresters for installation on incoming lines and power transformers, a protected level of 94 kv (62.5+6.2+25=94 kv) would be provided and a basic insulation level of 95 kv would be suitable for the impulse requirement of all apparatus in this station. The low-frequency wet voltage requirements would also have to be investigated in the final selection of porcelain insulation, since this wet requirement frequently is the determining factor in this class of substation and may provide a higher impulse characteristic than indicated by the basic-insulation-level requirement.

It will be seen from the values in table II that for bus insulators and indoor instrument transformers, it is necessary at present to select some equipment having a voltage rating of 25 kv in order to meet the insulation requirements and co-ordinate with the other apparatus. In the case of circuit breakers, the existing indoor types having interrupting ratings below 500,000 kva have impulse full-wave test values considerably below that of the other apparatus. Breakers of this interrupting rating are not generally available in the next higher voltage (23 kv) class.

Table III. Typical 138-Kv Substation

Insulation Design Basis: Basic Insulation Level 650 on Incoming Lines, 550 Elsewhere

() The greater margins between the protected level and the basic insulation level provided by these lower ratings may be utilized where applicable.

† Line-to-line voltage requirements determine the rating of this apparatus.

** Flashover rating. Impulse withstand tests not yet determined.

EXAMPLE III—TYPICAL HIGH-VOLTAGE SUBSTATION APPARATUS

Assume a 138-kv transmission substation in connection with a steam generating plant. The step-up transformers, of which there are two banks, are delta-connected on the generator side and wye-connected on the high-voltage side with the neutral solidly grounded. One of the transmission lines is an interconnection with another system and therefore has metering and regulating equipment on the line side of the breaker.

Following the procedure outlined, the possible dynamic overvoltages are analyzed at:

(*a*). The transformer connections—where it is desired to install a lightning arrester as close to the transformers as practicable

(*b*). The bus—to which it is considered that one transformer bank will always be connected

(*c*). The line sides of all breakers and metering equipment

Indoor—500,000 kva and up				95	110	150										
Synchronous machines†	7.0	13	21	41												

* Mininum average impulse flashover ratings 1½x40 wave. Withstand (full wave) voltage values now being established.

†Not impulse test value. Required protected level = 1.4 (2×rating+1 kv).

** In some ratings higher insulation levels are available.

‡ Negative five per cent tolerance allowable for "withstand" basis.

With the transformers solidly grounded at all times, the condition for maximum dynamic line-to-ground voltage is found to be with maximum system generation and with one transformer bank in service. This voltage is calculated to be 100 kv to ground, which allows the use of lightning arresters rated 121 kv or even 109 kv on the transformers or the bus. The basic insulation level selected for the transformers and bus is, therefore, 550 kv[3,4,8] based on a protected level of $463+46+25=534$ kv.

It is found by calculation that the maximum low-frequency voltage on the line side of the various breakers may be greater than that considered satisfactory for 121-kv protective devices and, therefore, 145-kv or at least 133-kv protective devices are required with a corresponding basic insulation level of 650 kv. All this is shown in table III.

Conclusions

1. The maximum dynamic *line-to-ground* voltage of the operating system existing at the apparatus under consideration is largely determinate in the selection of the basic insulation level required of that apparatus.

2. In selecting apparatus from the standpoint of its insulation strength, it is necessary to consider the insulation test levels to which the apparatus is designed, taking into account both the low-frequency and the impulse levels rather than merely the manufacturer's voltage rating.

3. The insulation strength of all types of apparatus should be clearly designated on the name plate in terms of the "low-frequency withstand" and "impulse withstand" voltage levels.

4. Analysis indicates that the schedule of basic insulation levels provided is adequate to fit the variety of requirements usually to be expected.

5. The basic insulation levels required of certain apparatus closely coupled and continuously associated with the protective device is not necessarily the same as that required of other apparatus in the same station which does not have the same degree of protection; for instance, power transformers as compared with line entrance switches or line potential transformers.

Discussion

Discussion will be found in the 1940 annual TRANSACTIONS volume and in the 1940 "Transactions Supplement" to ELECTRICAL ENGINEERING.

Proposed Standards for Outdoor Bushings

AIEE JOINT COMMITTEE ON BUSHINGS

THE electrical characteristics of bushings for different types of apparatus vary considerably for corresponding voltage ratings. This is partly due to the fact that different committees have handled the preparation of standards for different types of apparatus. Consequently the AIEE joint committee on bushings was formed in an effort to develop more consistent standards covering the electrical characteristics of bushings for all types of apparatus.

The joint committee was formed in February 1938 under the sponsorship of the AIEE standards committee. Its membership includes representatives from the three AIEE technical committees which deal with bushings, namely, the electrical machinery committee, power transmission and distribution committee, and the protective devices committee. The membership was carefully selected to provide tie-ins with the Edison Electric Institute-National Electrical Manufacturers Association Joint Committee on Co-ordination of Insulation and other committees interested in this problem.

Two major questions are involved in this problem, one, what electrical characteristics are required to meet conditions encountered in service and, two, how nearly do present-day bushings meet these requirements? Two subcommittees were formed to deal with these two questions separately. It was apparent that it would be necessary to prepare definitions and a test code and two other subcommittees were formed to prepare these.

In an effort to determine the requirements on an engineering basis a preliminary tabulation was prepared. The low-frequency characteristics were chosen to provide a satisfactory margin of insulation strength for overvoltages due to switching surges, overspeed, fault conditions, etc. The impulse characteristics were chosen to provide a satisfactory margin of insulation strength above the level of lightning protection which can be provided with modern lightning-protection equipment. The impulse characteristics selected are in accord with the values being considered by the Joint Committee on Co-ordination of Insulation. It was agreed that all of these characteristics should be expressed in terms of "withstand voltages" rather than "flashover voltages" in order to eliminate the variations and uncertainties involved in flashover tests.

Other tabulations were prepared independently showing the characteristics of present-day bushings and these values were compared with the requirements as mentioned above.

Table I. Proposed Standards for Outdoor Bushings

Recommended Minimum Withstand Test Voltages

Voltage Classification (Kv)	Low-Frequency Test, RMS Kv		Impulse Test, $1^1/_2$ x 40-μ Sec Full Wave (Positive or Negative) (Whichever Is Lower) (Crest Kv)
	1 Min. Dry	10 Sec Wet	
2.5	21	20	60
5.0	27	24	75
8.7	35	30	95
15.0	50	45	110
23.0	70	60	150
34.5	95	80	200
46	120	100	250
69	175	145	350
92	225	190	450
115	280	230	550
138	335	275	650
161	385	315	750
196	465	385	900
230	545	445	1,050
287	680	555	1,300
345	810	665	1,550

Explanatory notes:

1. These test values apply to outdoor bushings for all types of apparatus in the voltage classifications 23 kv and up.

2. For voltage classifications 15 kv and below, the test values apply to bushings for major apparatus such as large oil circuit breakers, power transformers, etc.

3. Lower test values may be assigned for bushings used for small oil circuit breakers, distribution transformers, etc. Further study is being given this phase of the subject by the committee.

After considerable study of these two tabulations the following recommendations for outdoor bushings have been agreed upon by the committee:

FUNDAMENTAL PRINCIPLES

(*a*). Bushings are generally integral parts of apparatus, but for the purpose of this study they are considered as separate items of equipment.

(*b*). Performance requirements of bushings shall be such as to permit standard tests on the apparatus with which they are used.

(*c*). Performance requirements are given on the basis of bushings without horn gaps, and under standard atmospheric conditions.

(*d*). Bushings are not intended as protective devices, although they may incidentally furnish partial protection to the apparatus upon which they are installed.

(*e*). The electrical strength characteristics are defined in terms of "withstand" test voltages.

(*f*). In all designs of bushings, the puncture voltage shall be greater than the flashover voltages for both 60-cycle and impulse waves under all standard test conditions.

PERFORMANCE REQUIREMENTS

Bushings shall be suitable for operating at their standard ratings:

(*a*). When and where the temperature of the cooling medium does not exceed 40 degrees centigrade.

(*b*). Where the altitude does not exceed 3,300 feet (1,000 meters).

The bushing requirements as specified in table I apply to outdoor bushings when mounted for testing in accordance with a specified arrangement yet to be determined in the test code.

Withstand Test Voltage

Withstand test voltage is the specified test voltage to be applied under specified conditions without bushing flashover.

For low-frequency voltage the values are expressed as root mean square for a specified time.

For impulse voltages the values are expressed as the crest of a specified wave of either positive or negative polarity, whichever gives the lower value. The impulse voltage shall be applied three times, and if any one (not more than one) of these three applications causes flashover, then the series of tests can be repeated. If in the second series of tests no flashover occurs, then the test causing flashover shall be considered a random shot and disregarded.

Paper 40-37, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Rationalization of Transmission-System Insulation Strength—III

Margins Between Basic Insulation Levels and Protectable Levels

PHILIP SPORN
FELLOW AIEE

I. W. GROSS
MEMBER AIEE

SINCE the subject of "Rationalization of Transmission-System Insulation Strength"[1] was first presented in a comprehensive manner in 1928, a great deal of constructive study and analysis have been devoted to the problem, and outstanding progress has been made in placing the insulation of an electric system on a more rational basis from the lightning or impulse viewpoint. Three groups have been most active in this work; the equipment manufacturers, the laboratories, and the users of equipment. Particular attention has been given by the manufacturers to increasing and protecting the impulse strength of various types of commercial apparatus. The laboratories have worked on obtaining fundamental impulse data on equipment impulse strength, and have set up approved methods of testing. Both the above groups as well as the users of equipment have co-operated in field investigations to determine the characteristics of natural lightning. Finally, the users, in co-operation with both the other groups, have worked untiringly to coordinate the entire work into a rationalized insulation system. This principle of insulation rationalization should not be lost sight of in the individual or group efforts on insulation co-ordination to develop particular equipment to meet definite impulse strengths. That is, the fundamental problem is one of rationalizing system insulation strength by co-ordinating the insulation strength of the various items of equipment constituting or forming a part of the transmission or distribution system.

Principles of Insulation Rationalization and Co-ordination

The general principle of insulation rationalization requires three steps.

1. The setting up of a group of insulation levels which can be assigned to various items of equipment.

2. Establishing steps of insulation strength, as seem reasonable, between various types of equipment to insure electrical breakdown, if it does occur, taking place at a predetermined location.

3. Establishing a reasonable margin between the voltage level held by the protective device (the protectable level) and the various basic levels themselves to insure that adequate protection is provided. It is with this latter consideration that the present paper is primarily concerned.

Co-ordination has too frequently been interpreted to mean bringing into the same order, or equality; so strictly interpreted it might well refer to the process of getting equipment to meet an agreed-upon level. Thus, a common level might be sought for all classes of equipment operating on a grounded 69-kv system, for example. But this attempt at oversimplification of the problem will not help its solution. If a distinction is to be made, then, the problem of deciding what types of equipment for given operating conditions shall have equal insulation, is one of co-ordination. On the other hand the setting up of basic insulation levels and applying the margins between levels and between different equipment in a given voltage class is rationalization.

The establishment of insulation steps between different classes of equipment on a given system is predicated on the assumption that the lower-insulated equipment will fail first, and without resulting in flashover or damage of the higher-insulated member. Likewise, the protective-device level should have a sufficient margin between the basic level (which controls the insulation strength of equipment in that level) to insure that all impulse or surge overvoltages which may reasonably be expected will be definitely limited by the protective device to a value below the basic level or to the values allowed for equipment in that level.

This idea was first proposed in 1928[1] and is as sound today as it seemed and was then. It is recognized, however, that the practical working out of it may be difficult if one of the criteria to be observed is to be the highly desirable one of imposing no undue sharp financial burden on the electrical industry. Hence, it will be necessary to be patient. But it would be a grave error to overlook the importance of getting the principle established as soon

Summary

The AIEE joint committee on bushings has attempted to determine the electrical characteristics of bushings on an engineering basis. The recommendations in this report are based on the theory that an ample margin of insulation strength should be provided above the voltages to which the bushings may be subjected in service, including dynamic overvoltages, switching surges, and lightning surges up to the level of protection which can be provided with modern lightning protective devices. This should make it possible to use bushings having the same electrical characteristics for transformers, circuit breakers, and all types of apparatus of corresponding voltage ratings because, if bushings have an ample margin of insulation strength above the level of protection which can be provided, there should be no need for any higher insulation strength for bushings in circuit breakers than in transformers or other apparatus. Lower values of insulation strength may be assigned for bushings for small circuit breakers, distribution transformers, etc., where space or other limitations may require smaller bushings and where a smaller margin of protection may be satisfactory.

The joint committee is continuing the study of bushings and will make additional recommendations covering indoor bushings as soon as agreement can be reached. They may also make recommendations covering bushings for lower-voltage ratings and possibly other characteristics of outdoor bushings.

Discussion

Discussion will be found in the 1940 annual TRANSACTIONS volume and in the 1940 "Transactions Supplement" to ELECTRICAL ENGINEERING.

as technical and industry conditions permit.

Considerations Involved in Insulation Margins

There are a number of important considerations involved in establishing margins between protectable levels and basic levels, or what may be called the safe or withstand strength of the equipment built to that level. Among these are the following which are discussed below:

1. Protective-Device Characteristics

Two factors must be considered in the protective device itself: first, its 60-cycle rating; and second, its protective characteristics. A protective device such as a lightning arrester or, in fact, a protective gap, may be considered to have a 60-cycle rating above which it is generally not considered safe or desirable to operate the device. It is well known that a lightning arrester operated continuously or even for short periods of time with a voltage across its terminals above its rating is subject to failure from dynamic overvoltage. Likewise, a protective gap has a lower limit of permissible setting below which the system to which it is applied, when subject to overvoltages such as switching surges and other transients which are not necessarily dangerous to the system insulation, may experience excessive interruptions, thus preventing the rendering of adequate, not to say high grade, service. The normal-frequency voltage of the system, therefore, determines to a large extent the minimum lightning protection which it is possible to apply.

In considering the protective characteristics of the arrester, a number of factors must be considered, on some of which we have little or no information at the present time. These factors are:

(*a*). The maximum lightning current which the arrester may be called upon to discharge. Considerable progress has been made in obtaining information on the magnitude and frequency of such currents in actual field installations.[2,3]

(*b*). The protective characteristic of the arrester (IR drop) varies with the magnitude and rate of current rise through the arrester. The rate of rise of currents through arresters in service is unknown.

(*c*). Again, the lightning-arrester characteristic is affected by the rate of voltage rise of the incoming surge and the arrester-gap breakdown under this condition may be important.

(*d*). A manufacturing tolerance has to be allowed for, as no two arresters of identical characteristics, even made by one manufacturer at the same time, can be relied upon to have exactly the same electrical characteristics.

(*e*). While the arrester may hold the lightning voltage at its own terminals to a predetermined value, under given conditions, just how far distant (circuit feet) it is possible to supply this protection is one of theoretical calculation only at the present time, and again depends upon the rate of voltage rise of the incoming surge and upon voltage reflections.

2. Frequency of Overstress Voltages

The normal or excess margin of insulation over its rated or tested value may have to be taken advantage of in setting up margins between basic and protectable levels. For example, if currents of 15,000 to 30,000 amperes are discharged by the arrester only once in 10 or 20 years, it may be more economical to overstress some equipment insulation once during this period as a result of such a surge, rather than attempt, by expensive additional insulation to maintain the basic insulation level above this value under such conditions.

3. Effect of Aging or Other Deterioration of Insulation

It is well known that some classes of equipment will deteriorate with age even though given what may be considered ordinary or even high-grade care and maintenance. The presence of carbon and moisture in the insulation, and natural aging tend to weaken the insulation of many types of equipment, and this must be considered in arriving at a margin between the protectable level and the equipment strength.

4. Degree of Protection Justifiable and Sought

Finally and perhaps least definite of all, is the degree of protection which it is desired to obtain. Probably no system of insulation steps, even with protective devices, can be practically and economically applied which will preclude an occasional failure of some piece of equipment. In other words, 100 per cent protection is practically, and certainly economically, impossible. But there are differing degrees of near perfection, and different classes of service will each justify its separate different degree of near perfection. Therefore, it is quite apparent that in arriving at the protection margins to protect the basic levels, consideration must be given to what is a reasonable degree of protection to be expected and economically justified under a given set of conditions.

Determination of Protectable Levels by Use of Lightning Arresters

The determination of the margin between protectable levels and basic insulation levels obviously calls for a determination of the protectable level as well as the basic insulation level. If the protectable level is to be obtained by the use of a lightning arrester it is however, necessary to have a clear understanding of the basis of applying the arrester and of determining its performance. This has been done in the analysis which follows:

1. The protective characteristic of the lightning arrester is based on the arrester discharge at 5,000 amperes with the accepted 10–20-microsecond time characteristic. This value of 5,000 amperes is one which, as indicated by recent extended field tests,[3] may be encountered with sufficient frequency to justify its use.

2. The protective voltage levels of the arrester are taken as the maximum values (as distinguished from minimum or average values) for all arresters, whether distribution, line, or station type.

3. In applying arresters on a power system, it is desirable that the arrester maximum permissible rating should be not lower than the maximum power-frequency voltage to ground expected on the system under the most severe operating conditions.

Following this line of reasoning, the maximum rating of lightning arresters applied on an effectively grounded-neutral system has, for purposes of this analysis, been so chosen as to be not less than 1.3 times[*] the highest operating voltage (line to ground) to allow for the higher voltage which may exist under fault conditions. Where more severe conditions exist, it has been assumed that they will be considered as special cases.

4. In considering the entire group of normal system voltages, the numerical values have been increased on a fixed percentage basis to take care of the probable higher operating voltages to be expected on some systems throughout the country; and on account of system voltage regulation, the percentages of increase used are as follows:

For systems up to 8.3 kv rated voltage between phases, 20 per cent increase. For system voltages above 8.3 to 15 kv inclusive, 10 per cent increase; and above 15 kv, 6 per cent.

System voltages where hydro generation predominates are considered as requiring special consideration, although later discussion of obtainable insulation margins touches on this point.

5. In applying rod gaps as protection to the basic levels, a gap spacing equivalent to $3^1/_4$ times[6] the line-to-neutral voltage has been used. It is realized that this results in physical spacings so small in the lower voltage class of equipment that they may be considered impractical in this range.

In applying arresters to any power system, the one important criterion, that the 60-cycle voltage across the lightning arrester should not exceed its maximum rating, has been carefully observed. For arresters on an isolated-neutral system, it is assumed that so long as the arrester maximum rating is not below the power-frequency line-to-line voltage across the arrester at any time, the arrester itself is self-protected against power voltages. This reasoning is based on the large amount of experience throughout the industry in applying arresters on this basis. In applying arresters on an effectively grounded neutral system, on the other hand, recognition is given to the fact that the system line-to-ground voltage may, during fault conditions, considerably exceed normal. To allow for this the system line-to-ground voltage is increased 30 per cent, and this, as previously discussed, it is believed is sufficient to give the arrester dynamic-voltage protection in the preponderating percentage of cases, where system neutrals are effectively grounded. While it may be desirable in actual practice to add a small margin above this figure, the above basis has been used in this analysis.

Protection of Basic Insulation Levels—Margin Between Basic Insulation Levels and Protectable Levels

Table I has been prepared in an attempt to show what margins of protection to the basic insulation levels are possible by the use of protective devices on a sound engineering basis, in a range of system voltages normally encountered. It should be clearly pointed out, before discussing this table, that the analysis given herewith deals with the protection of the basic insulation levels themselves. The consideration of whether or not equipment is protected will, of course, depend on whether or not it conforms to the definite basic insulation level to which it has been assigned and the margin of protection existing above the protectable level. As will be brought out in the succeeding discussion, equipment conforming to any one of the basic insulation levels can in many cases be used in closely associated levels, and reasonable protection supplied unless the equipment itself cannot by virtue of its dynamic-voltage functional characteristics be so applied. (For example, a 2,300-volt transformer could not be used on a 15-kv system even if its basic insulation level could be adequately protected.)

Referring now to table I, in reference *a* is given the "insulation reference class" which conforms quite closely to the "preferred system voltage" now in common use. The second line (reference *b*) gives the highest normal system voltages which may be expected to be encountered on the distribution and transmission systems throughout the country. These have been selected on the basis of the operating voltages now in use by a great many of the larger utility companies.

To arrive at the 60-cycle basis for applying arresters to an ungrounded system, reference *c* has been developed by increasing the "highest normal system voltages" (reference *b*) by one of the three percentages of 20, 10, and 6 as mentioned above. By converting these to line-to-neutral values the voltages for the effectively grounded-neutral system have been obtained (reference *h*). In references *d* and *i*, the lightning arresters have been selected for both isolated and grounded-neutral systems using the maximum permissible rating for commercial arresters as now being made. The protective characteristics, that is, the maximum voltage permitted by the arrester at 5,000 amperes discharge of these two groups of arresters (references *d* and *i*) are given in references *e* and *j*. Where double figures occur in any column, the first figure is for distribution or line-type arresters, and the second figure for station-type arresters. All these numerical values are the maximum for arresters of each class indicated, and conform to published data developed by and agreed upon by arrester manufacturers as representative of their product.*

---

[*] This is the figure that applies except in a very few special cases on our system. For fuller discussion of overvoltages see references 4 and 5.

Following the line of thought that a "safety factor" should be provided to take into account the large number of variables as enumerated above, the arrester *IR*-drop characteristic has been increased by a margin of ten per cent plus a flat value of 25 kv. These might be considered as the highest voltage levels that need to be considered in any study of basic insulation levels. Figures so arrived at for both isolated-neutral and grounded systems are given in references *r* and *s*.

In reference *q*, the proposed basic impulse insulation levels now being considered have been listed for the various insulation classes noted in columns 1 to 20 of the table. A comparison of the basic insulation levels in reference *q* with the highest lightning-arrester levels already referred to in references *r* and *s* shows that there is a reasonably close agreement between the basic insulation levels and the lightning-arrester characteristics plus margins (reference *r*) even for the isolated-neutral-system arrester, although it must be admitted that the line-type arrester for isolated-neutral service shows an almost consistent deficiency of margin between the basic insulation level and the highest voltage level to be expected from arrester performance figured on that basis. This is admittedly, however, a method of check that goes to some extremes in assumption of unfavorable protective conditions.

To determine the actual margin between the proposed basic insulation levels and the arrester *IR* drop at 5,000 amperes, references *f* and *k* have been developed for isolated and grounded-neutral systems respectively. Reference *f* shows the margins ranging from 19 kv in the low insulation class, with a general upward trend to 150 kv in the 345 class for station arresters. Line-type arresters do not show up so well however, although they do show a positive margin in their entire range of applicability. One point of distinct interest here is that shown in reference *k* which gives the margins of basic insulation levels over lightning arresters for grounded-neutral service. Here, the margin starts at 19 kv and increases to 480 kv in the 345 class. From the 2.5 class up, the margin between the basic insulation level and the lightning arrester ranges from equality to as high as 3 times as great for station arresters, and as high as 30 times as great in line arresters, for grounded-neutral systems when compared with the isolated-neutral system.

If higher margins than given in reference *f* are desired between basic insulation levels and lightning arresters for isolated-neutral service, this can be accomplished by using basic insulation levels in the next higher level. Margins obtainable in this way are shown in reference *g*. It will be noted that they are quite ample even with line-type arresters.

Again, where the system operates with an effectively grounded neutral, but abnormally high voltages may occur because of hydro generation, system extent, or other conditions, it is possible to use the proposed basic insulation level in the assigned insulation class and arrester in the next higher class, thus supplying the required margin of 60-cycle strength for the arrester and still offering a high degree of protection of the basic insulation level as shown in reference *l*. Many of these margins for the various insulation classes are of the same order of magnitude as is possible by applying standard arresters to isolated-neutral systems (comparison of references *f* and *l*). There is, of course, one notable exception in the 46 class; but for the 69 class and above, the protection thus afforded is equal to or better than that supplied on the isolated neutral system.

This same reference *l* shows the margins which are possible by using the appropriate arrester for grounded-neutral systems, and basic insulation levels in the next lower insulation class. For example, in the 138 class, it is shown that by using 115-class insulation on a 138-kv system with grounded-neutral arrester rated at 109 kv, there is a margin of 130 kv. This, of course, is less than the 230-kv margin obtained when using standard 138-kv insulation with the grounded-neutral arrester. However, it is more than the 90-kv margin obtained in using the standard 145-kv arrester on the isolated-neutral system.

The correlation of the proposed basic insulation levels with protective gap characteristics is given in references *m*, *n*, *o*, and *t*. It needs to be pointed out, however, that the gap data at low spacings in the range of insulation reference classes from 0.6 to 8.7, involving as they do gaps of one-inch spacing or less, are not presented as being particularly reliable or representative of gap spacings which any operating company would be willing to consider as practical in these voltage ranges.

The protective characteristics of a rod gap have been set up on a basis of using flashover data with a 1x5 negative impulse, and the average values of 50-50 flashover of such gaps have been increased 15 per cent to allow for tolerance of performance under practical conditions. This gives a figure which may be comparable to the *IR* drop characteristic of arresters at 5,000 amperes. This particular procedure in arriving at gap characteristics may be questioned, but it is presented here merely for comparative purposes to show the relative degree of protection which can be afforded by rod gaps using assumptions believed to be reasonable, and available data. It will be noted from reference *p* that margins of protection over the proposed basic insulation levels are positive up to the 69 reference class but become negative beyond this point. It should be remembered however, that these margins are based on a gap spacing corresponding to $3^{1}/_{4}$ times the maximum expected line-to-ground system voltage. It is entirely possible where experience with difficulties from line tripouts due to switching surges are favorable, or where the requirements of service continuity are not too stringent, to reduce the gap spacing and thus give positive margins, in some of the higher-voltage classes.

Practical Experience in Applying Lightning Protection

As previously reported[10] there was initiated some five years ago on the system of the American Gas and Electric Company a practice, applied to large power transformers, of locating directly on the transformer tank a lightning arrester correlated with the transformer strength. It is interesting to review the performance record since that time of transformers protected in this way, and compare the margins with those arrived at from the above analysis.

During the past four years there have been installed on the American Gas and Electric Company's 132-kv interconnected system nearly 700,000 kva of transformers which have been protected by lightning arresters mounted either directly on the transformer or as close as possible thereto. A review of the margins between the full-wave transformer test and the lightning-arrester *IR* drop at 5,000 amperes for the 132-kv windings of these transformers indicates values from approximately 40 kv to 205 kv. All of these 132-kv windings conform to the 115-kv insulation class so far as voltage tests were concerned, some were delta connected and others built with graded insulation for grounded neutral service, with an appreciable saving in first cost.

---

* By and large these values have been checked by laboratory test.

With the use of standard transformer insulation on the 66-kv systems a margin of 30 kv was obtained between the strength of various transformers applied on them during this period and lightning arrester characteristic; in the 44-kv class, the margin was 33 to 96 kv; in the 34.5-kv class 37 to 80 kv; and in the 22-kv class 39 to 55 kv. It will be noted from the above figures that it has been possible to obtain with standard insulation on transformers as offered today, a substantial margin between the transformer full-wave test strength and *IR*-drop characteristics of lightning arresters of recent design. Further, in the higher-voltage class of 138 kv, it has been possible to utilize impulse insulation one class below the standard 138-kv class and still obtain margins which appear to be satisfactory. It should be pointed out in this connection, however, that in nearly all these cases of graded insulation using insulation in the next lower class, the lightning arrester has been mounted directly on or very close to the transformer.

On the 132-kv system, margins which we have been able to obtain in the past have not been quite as high as those indicated in table I or as obtained during the past four years. There are several reasons for this. One is that present-day arresters undoubtedly have better characteristics than those made several years ago thus permitting of larger margins, and another is that we have permitted ourselves to work on closer margins because we have generally impulse tested the very arrester which was used in service, while mounted directly on the transformer. Under such actually checked margins lower values are obviously still safe. It is further interesting to note that of some 750,000 kva of transformer capacity installed during the past four years involving circuits of 22, 33, 44, 66, 88, and 132 kv, not a single case of transformer failure has occurred where the transformer strength has been built up to the present insulation standards and protection supplied by modern lightning arresters with margins of the above indicated order.

Summary and Conclusions

1. The solution of the problem of rationalization of system insulation has advanced considerably since it was first proposed some 12 years ago, and the currently discussed series of basic insulation levels is a significant contribution toward its solution.

2. The proposed basic impulse insulation levels (reference *q* of table I) appear to provide a sufficient number of steps and their level values are suitably chosen so that modern arresters can be applied to protection of equipment built to these basic levels, and adequate margins realized under practically all conditions likely to be encountered in power-system operation.

3. The spacing of the basic-insulation-level steps has been so arranged as to make possible the securing of considerable flexibility in the choice in the margins of protection of equipment built to these levels without the assumption of burdensome economic handicaps.

4. While the margins between arrester characteristics or protectable levels and basic insulation levels appear adequate, considering the uncertain and unknown factors in lightning voltage surges which may be imposed on apparatus and the performance of a protective device under these conditions, caution is necessary. Particularly is this true if the arrester is expected to provide adequate protection to equipment located at some distance from the arrester as is required in some cases.

5. As a reasonable margin between the basic insulation level and lightning-arrester *IR*-drop characteristic, for general application, it is suggested that the arrester *IR* drop at 5,000 amperes increased by ten per cent and 25 kv should not be greater than the basic insulation level. This will influence in some cases the type of arrester chosen. Where the arrester is located at or close to the equipment to be protected, practical considerations may be permitted to allow acceptable margins below the value so arrived at.

6. With the acceptance of the proposed basic insulation levels (reference *q*, table I) the problem of assigning insulation strength to all classes of equipment in terms of these levels on an engineering and economic basis should not be difficult if a broad, industry-wide point of view is taken of the insulation rationalization problem.

7. Eventually it will be found necessary and desirable, in order to complete the solution of the problem of rationalization of system insulation, to provide definite margins in the levels of different equipment forming part of any given transmission system. It may be that this can best be done as part of the natural development which started with the work of investigation and determination of impulse characteristics of equipment, continued with the investigation of natural and system overvoltage phenomena, to be followed by the establishment of proper basic insulation levels and by the development of equipment to protect these levels and, finally, completed by the assignment of insulation strength to various equipment groups in terms of these levels. Whether such margins in levels for different equipment on one system should be established at the time the problem of assignment of insulation strength to various equipment groups in terms of basic insulation levels is carried through, or whether it will be best to await the experience gained by the assignment of practically co-ordinated levels for all the items of various equipment in a voltage class, is something that need not be determined at the present. The problem, in any case, is well enough in hand to permit patience with a view of not only allowing for integrating further experience, but also of making certain that no heavy burden is thrown on any portion of the industry concerned in this problem.

Insulation Co-ordination

ONE of the early steps taken by the electrical industry, in an attempt to help solve the insulation-co-ordination problem was the formation of the National Electric Light Association (now Edison Electric Institute)-National Electrical Manufacturers Association Joint Committee on System Insulation Co-ordination in 1931. Before relating the work done by this committee, to acquaint the industry with what has been done to date and the present status of the work, it may be well to comment briefly, on what is meant by "insulation co-ordination."

It was generally recognized some ten years or so ago, as brought out by many papers in the technical press then and later, that the insulation strength of various classes of equipment was assigned not on the basis of the electric system as a whole, but rather on the requirements, as then understood, of each class by itself. This situation became strikingly evident in regard to the lightning, or impulse, strength of equipment which, until some 13 years ago, received comparatively slight consideration, largely because until then very little was known about the magnitude of lightning voltages on electric systems and the ability of insulation to withstand such voltages.

As information was obtained on both of these factors, it soon became apparent to some that it should be possible to arrange the impulse or lightning strength of equipment on any electrical system in a rational manner related to that particular system's requirements and so proportioned that electrical breakdown from lightning, if it did occur, could be confined to a predetermined location where the least damage would result to apparatus and service.

Closely associated with this idea, which basically required insulation steps or margins between the different classes of equipment, was the idea of setting up agreed-upon insulation levels. These levels, it has always been believed, quite logically should be based on the protection level afforded in the various voltage classes by available protective devices such as lightning arresters. This line of reasoning postulates then the setting up of levels which can receive a reliable degree of protection from the protective device, thus tending to minimize system service outages. But it goes further, and permits assignment to the different pieces of equipment of such strengths as should localize the failure, if such occurs, at that point in the electrical system where the least damage will result. In short, the term "insulation co-ordination" may be defined as the process of setting standards of insulation strength and assigning them to all the items of equipment in the various insulation classes in such a manner as to produce from an economic and operating standpoint both a maximum of protection and, if failure results, a minimum damage to the system.

Progress in Solving the "Insulation Co-ordination" Problem

The first step of the joint committee was the adoption in 1931 of a statement of principles which said:

> "The co-ordination of insulation involves three steps:
>
> "1. Establishment of insulation levels.
>
> "2. Specification of insulation strengths of all classes of equipment in established insulation levels.
>
> "3. Allocation of the insulation levels to the nominal system voltages, taking into account all operating and environmental conditions."

The establishment of levels on an impulse basis with definite kilovolt values given, was covered by a committee report[1] in 1937. The second step was undertaken in 1937 by the formation of the "Insulation Strength of Equipment Subcommittee of the EEI-NEMA Joint Committee on Co-ordination of Insulation" which has since been actively working on the problem. As a result of its work, it appears that the basic impulse insulation levels agreed upon in 1937 should now be reviewed in the light of our present knowledge, and the recent developments in the art. This is the subject of this paper.

Basis for Impulse Insulation Levels

In the 1937 report, basic impulse insulation levels were recommended which were the outcome of a study by a subcommittee of the insulation levels of existing substations and the performance obtained with those levels. The subcommittee did not select for the basic levels the best-insulated systems, but rather the average of a number of systems that were known to have a good operating record over the years. The values selected, therefore, were not unreasonably high but represented good general practice at the time of the survey.

In addition the then proposed values were checked against the performance characteristics of lightning arresters then available, and the flashover characteristics of rod gaps in use for commercial testing of transformers. This seemed to be a practical and sound basis on which to set up the levels.

Up to the time of the 1937 report, it had been customary to express impulse insulation strength in equivalent "inches of rod gap." The reason for this was that the testing technique of the various laboratories had not yet developed to the point where they could agree on the flashover value in volts of a rod gap. By 1937, however, this difficulty had been overcome and it was possible, therefore, to express the basic impulse insulation levels in volts. Considering the evolution of this step from rod gap and insulator testing, it was rather natural that the conversion from gap spacings to volts should be on a 50-50 flashover basis, that is, volts corresponding to gap spacings giving 50 per cent flashover and 50 per cent full wave when subjected to a standard impulse wave.

Since that time experience has been gathered in applying the values to actual practice. This has shown that the basis originally chosen requires clarification and adjustment.

It is not practicable to subject most types of apparatus to a series of flashover tests to demonstrate their insulation levels. Rather, a piece of apparatus is designed to withstand a certain impulse voltage when tested in parallel with a gap set for that particular voltage. It developed, then, that the impulse strength of apparatus was determined on one basis (withstand basis) and the required level was given on another basis (flashover basis). In order to reconcile these differences, it

Paper 40-83, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 22, 1939; made available for preprinting December 20, 1939; released for final publication March 27, 1940.

PHILIP SPORN, vice-president in charge of engineering, American Gas and Electric Service Corporation, New York, N. Y., is chairman of the EEI group and C. A. POWEL, manager of industry engineering department, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa., is chairman of the NEMA group of the Joint EEI-NEMA Committee on Insulation Co-ordination.

[1] For numbered reference, see end of paper.

was necessary, therefore, to include a negative tolerance in the definition of basic insulation levels for demonstration of acceptability of equipment.

Since the basic impulse levels were proposed, manufacturers' testing laboratories have been working on refining impulse testing technique and the determination of the impulse strength of various apparatus. On the basis of this improved testing technique, it has been found quite recently that some of the porcelain insulators in bus and switch assemblies do not meet the basic impulse level proposed for the system voltage on which they are frequently used. As these comprise an important part of the system insulation, and as some insulators with seemingly inadequate insulation (as indicated by the suggested impulse levels) have given good performance in service, it is felt that further consideration should be given to that problem.

Definition of Basic Impulse Insulation Levels

The committee, therefore, set about redefining the 1937 basic insulation levels and put the values on a "withstand" rather than a "flashover" basis to eliminate the need for a tolerance factor.

To indicate how this redefining was accomplished, the old and new definitions are given below:

Old Definition

"Basic insulation levels are reference levels expressed in impulse crest voltage with a standard wave not longer than a 1.5x40-microsecond wave.

"Note: Apparatus insulation as demonstrated by suitable tests shall be equal to or greater than the 'basic insulation levels'. Due to the present limitation in testing, a tolerance of minus five per cent may be allowed when making full-wave tests on specified types of apparatus."

New Definition

"Basic impulse insulation levels are reference levels expressed in impulse crest voltage with a standard wave not longer than 1.5x40-microsecond wave. Apparatus insulation as demonstrated by suitable tests shall be equal to or greater than the basic insulation level."

To clarify what is meant by "withstand basis," the definitions prepared by the laboratory subcommittee and amplified in a separate report are repeated.

Withstand Voltage (for an Impulse)

"The withstand voltage of a test specimen under an impulse of any given wave shape, polarity, and amplitude, which does not cause disruptive discharge on the test specimen, is the crest value attained by that impulse."

Table I. Basic Impulse Insulation Levels

Reference Class (Kv)	Basic Level Based on Old Definition (Kv)	Basic Level Old Definition Reduced 5 Per Cent (Kv)	Proposed New Basic Level* (Kv)
1.2	32	30	30
2.5	53	50	45
5.0	63	60	60
8.66	80	76	75
			95
15	100	95	110
23	150	143	150
34.5	190	180	200
46	250	238	250
69	360	342	350
92	470	447	450
115	570	542	550
138	680	646	650
161	790	750	750
196	950	900	900
230	1,100	1,050	1,050
287	1,360	1,300	1,300
345	1,620	1,550	1,550

* These levels represent definite steps between which no intermediate values will be recognized. It should be noted that the levels are proposed and still under consideration of the joint committee.

Note: Attention is called to the fact that equipment carrying a power-frequency voltage rating which is numerically the same as the "Reference Class" in table I is not necessarily required to have the impulse levels given in the table.

Critical Withstand Voltage (for an Impulse)

"The critical withstand voltage of a test specimen under an impulse of any given wave shape and polarity is the crest value of that impulse when its amplitude is adjusted to be just below disruptive discharge on the test specimen."

Rated Withstand Voltage* (for an Impulse)

"The rated withstand voltage of a test specimen is the crest value of an impulse of given wave shape and polarity, to be applied under specified conditions without disruptive discharge on the test specimen."

New Proposed Basic Impulse Insulation Levels

As a result of the foregoing considerations it is proposed to revise the 1937 levels as indicated in table I. The second column gives the 1937 levels which were on a 50-50 flashover basis. The third column gives the 1937 values reduced five per cent to put them on a "withstand" rather than a flashover basis. And the fourth column, which represents the new proposed levels, is practically the same as column three except that the figures have been rounded off to the nearest 5 kv, and further slightly altered in several cases to plot on a smooth curve against the "Reference Class." Also one new basic level of 110 kv has been added. In the first column the heading "Reference Class" has been used and values given to facilitate a comparison of the proposed levels with previously published[1] data.

Considerable discussion has taken place as to the desirability of associating the impulse levels directly with operating voltages; and two radically different opinions exist on this point. One is, that since lightning voltages encountered in service are not dependent on the operating voltage, the impulse levels should not carry what purports to be an operating voltage rating; rather, arbitrary references such as *A*, *B*, *C*, etc., or 1, 2, 3, etc., might well be used for identification. The other point of view is that to omit the operating voltage designation will result in considerable confusion in the industry. It is outside the scope of this paper to discuss this phase of the problem here. Certain it is, however, that a co-ordinated system of insulation levels is desirable, and the values as given in the 1937 committee report have been extensively used in producing better insulation co-ordination on many electric transmission systems which exist today.

There are, however, still individual items of equipment that do not meet the 1937 basic levels, and in some cases, notably apparatus insulators and assemblies, some are low. The modification of designs covering these devices to meet the proposed levels cannot be undertaken without considering the economic burden on the electric industry. However, it may not be detrimental to the co-ordination program if they do not meet the proposed levels until further experience and discussion on this phase shows the desirability of making them conform to such levels.

Committee Representation

The formation of the joint committee on co-ordination of system insulation, started in 1931 through joint action of NELA (now EEI) and NEMA brought together for a study of the problem two vitally interested groups, one the users and system designers, and the other the manufacturers. Within the last few months the AIEE has agreed to join the above two groups in carrying on the work. As soon as the AIEE representatives are appointed the committee will function as a triple joint committee under the sponsorship of AIEE, EEI, and NEMA.

Summary and Conclusions

1. The adoption of basic impulse insulation levels by committee action in 1937 has actively stimulated the work of designing and

Recommendations for High-Voltage Testing

EEI-NEMA SUBCOMMITTEE REPORT

I—Introduction

(a). Scope of Committee Work

THIS subcommittee was established to study laboratory differences in results and methods in high-voltage testing and to propose laboratory technique to remedy these differences. Line-insulator, gap, and apparatus-insulator testing have been included in the scope of subcommittee activities. Some two years ago the subcommittee reported on flashover characteristics of rod gaps and insulators.[1] Since then continued work on high-voltage problems has resulted in a markedly improved understanding of the situation and some further recommendations have been agreed upon. Section II of this paper gives general recommendations for impulse testing and Section III outlines the scope of the Committee's recent activities and presents additional recommendations, particularly as to humidity corrections. All these activities are definitely related to the major problem of insulation co-ordination.

(b). Insulation Co-ordination

Insulation co-ordination is the correlation of the insulation strength of all the electrical equipment in a station or substation to meet a specified level or levels. In general, present practice is to have all the equipment meet a certain level of strength selected so that a protective device will control the path of discharge or flashover. Fundamentally, the purpose of impulse testing is to determine the relative performance of apparatus when subjected to surges such as those caused by natural lightning. In practice the co-ordination of apparatus insulation for impulse voltages is determined by tests which

(*a*). Demonstrate the insulation strength of the apparatus

(*b*). Demonstrate the protected voltage level established by the protective equipment

Uniform testing-equipment characteristics and testing methods and technique are, therefore, very desirable.

II—General Recommendations for Impulse Testing

The following practices related to impulse-voltage-testing equipment and methods have been found satisfactory and are recommended for immediate and general use, where standards for particular types of apparatus do not apply.

(a). Impulse Generator.

A composite schematic diagram of the discharge circuit of a surge generator is shown in figure 1. In many cases, however, some of the elements shown are omitted or are negligible.

A capacitance C_1 is charged by a rectifier to a voltage which produces discharge through a gap into a group of resistors. The impulse test voltage appears across resistance R_4, across which the test specimen is connected.

The capacitance C_1 may consist of several groups of capacitors which are charged in parallel and discharged in series by means of the Marx circuit. The inductance L_1, which is made as small as possible depends upon the physical design of the generator and the total length of the discharge circuit. The resistance R_1 consists of the inherent series resistance of the capacitors and connections and often additional lumped resistances. Additional inductance L_2 or resistance R_2 may be added at the generator terminal for wave-form control. R_3 is a resistor, for controlling the length of the wave, which may be used in addition to R_4 to obtain better regulation of the test voltage especially for short waves. Resistance R_4 may be used alone to control the length of the wave and it simultaneously serves as a voltage divider when a cathode-ray oscillograph is used for recording the wave shape. Capacitances C_2 and C_4 represent the electrostatic capacitances to ground of the high-voltage parts and leads. Included in C_4 are the capacitance of the test specimen and any additional load capacitance that may be required for correct wave shape. L_4 represents the inductance of the test piece. For some test specimens L_4 greatly influences the wave shape.

Because test pieces vary widely as to impulse characteristics and successful testing requires that certain recommended waves be obtained, adjustments of circuit constants are frequently required. Resistances R_2, R_3, and R_4, capacitance C_4, and inductance L_2 should be capable of adjustment.

For practical reasons one terminal of the impulse generator is solidly grounded during the discharge. Impulse voltage of either polarity is obtained by changing

---

Paper 40-38, prepared by C. M. Foust and P. H. McAuley as a report by the subcommittee on correlation of laboratory data of the Edison Electric Institute-National Electrical Manufacturers Association joint committee on insulation co-ordination, and presented at the AIEE winter convention, New York, N. Y., January 22-26, 1940. Manuscript submitted November 16, 1939; made available for preprinting January 2, 1940; released for final publication March 27, 1940.

Personnel of EEI-NEMA subcommittee on correlation of laboratory data: J. E. Clem, chairman; A. C. Monteith, secretary; C. M. Foust, H. A. Frey, J. T. Lusignan, P. H. McAuley, K. B. McEachron, P. L. Bellaschi, and L. H. Hill.

[1] Electrical Engineering (AIEE Transactions), June 1937.

---

redesigning equipment to meet these levels.

2. Redefining the basic levels to require equipment to withstand the specified test (instead of permitting flashover at the specified values) requires a revision of the values adopted in 1937.

3. The proposed new basic levels appear to be based on sound fundamentals of the insulation co-ordination problem, and their early acceptance should result in a distinct forward step in carrying on the work to a conclusion.

4. It is generally understood that equipment carrying a power-frequency voltage rating which is numerically the same as the "Reference Class" in table I is not necessarily required to have the impulse levels given in the table. Setting up levels of a given value is one problem; assigning equipment to these levels is a separate and distinct one.

5. Discussion is invited by all those interested in this subject, particularly on those aspects of the problem dealing with the proposed new levels, designation of levels, and experience with the use of insulation conforming to or radically different from the levels adopted in the 1937 report.

In practice R_3, R_4, L_2, C_4, and L_4 may be omitted or may be negligible compared to the other constants in a particular generator

the polarity of the charging circuit of the impulse generator.

(b). IMPULSE WAVES

The most commonly used impulse wave is the 1.5x40-microsecond wave which is being considered for certain standards. The 1x5- and 1x10-microsecond waves have been used occasionally in the past. In the interests of simplification and uniformity, it is recommended that the 1.5x40 wave be universally adopted with proper tolerances for individual apparatus testing codes.

The International Electrotechnical Commission recognizes two waves respectively 1x5 and 1x50 microseconds. Also particular tests sometimes require specified wave fronts such as 50, 100, or 1,000 kv per microsecond.

In figure 2 is illustrated a typical impulse wave. For practical reasons a virtual zero-time point is established at O_1 and determined by a line drawn through the $0.1E$ and $0.9E$ points on the wave front. For the 1.5x40 wave O_1X_1 is 1.5 microseconds and O_1X_4 is 40 microseconds. Thus the standard 1.5x40 microsecond wave rises to crest voltage in 1.5 microseconds and decays to half crest value in 40 microseconds. In this way an impulse wave is specified as a T_1xT_2 wave where T_1 and T_2 are O_1X_1 and O_1X_4 respectively.

If the front is difficult to determine the virtual time-to-crest may be given as a constant such as 1.5 times the interval between the $0.1E$ and $0.9E$ points on the wave front. The proposed standard for transformers calls for 1.5 and, in this case, therefore, the virtual time-to-crest is $1.5X_3X_2$.

The actual recorded wave should conform to the specification. Spurious oscillations on the wave front should be damped out by a sufficient amount of resistance R_1 or R_2 to permit accurate measurement and analysis. The amplitude of such oscillations should not exceed five per cent of the fundamental wave.

Variations from the standard 1.5x40-microsecond wave shape should not exceed ±0.5 microsecond on the wave front and (+10, −0) microseconds on the wave tail. These figures refer to the test wave when no disruptive discharge occurs and where a particular apparatus standard involved does not specify a different tolerance. When the test piece characteristic is such that a wave within these limits cannot be obtained, the actual wave shape should be specified.

(c). IMPULSE FLASHOVER

In testing an insulation specimen a range of voltage is usually found in which disruptive discharge may or may not take place, the percentage of voltage applications which cause disruptive discharge rising from zero at the lower edge of the range to 100 at the upper edge. When no disruptive discharge occurs a *full wave* is obtained. When a disruptive discharge occurs a *chopped wave* is obtained and this chopping may occur on the tail, at the crest, or on the front of the wave depending upon the voltage.

The *critical flashover voltage* of a test specimen under an impulse of a given wave shape and polarity is the crest value of that impulse when its amplitude is adjusted to cause flashover on 50 per cent of the applications.

(d). VOLT-TIME CURVE

The volt-time curve is a graph of the crest values of flashover voltage against the time to flashover for a series of impulse applications between the full-wave test and front-of-wave flashover. The points should be chosen and distributed to fit the volt-time curve throughout this range. Ordinarily 20 to 40 points are desirable where air insulation is involved, but fewer points will give a good approximation of the curve and will suffice for the breakdown of expensive samples. The points for the volt-time curve are obtained from cathode-ray oscillograms of impulse discharges.

(e). FRONT OF WAVE TESTS

Apparatus may be tested with flashovers occurring on the front of the wave. The rate of rise or steepness of the front may be varied by changing the circuit constants or the generator voltage or both.

The rate of rise is specified by the slope of the line through the $0.1E$ and $0.9E$ points on the front, figure 2, in kilovolts per microsecond and is called the effective rate of rise. The average rate of rise is often considered a more significant figure in front-of-wave tests. It has been defined as the slope obtained by dividing the crest voltage of the wave by the time to flashover measured from virtual time zero.

In some cases the lower part of the wave rises gradually to 30 or 40 per cent of the crest voltage and rises more rapidly thereafter. The $0.1E$ point does not give a true indication of the wave when used in determining rate of rise. The tangent for the more rapidly rising portion of the wave should be used in determining the rate of rise in this case.

It is recommended that, at least until it is possible to standardize more definitely on front-of-wave testing technique, both time-to-crest and time-to-flashover together with the method of specifying the rate of rise be recorded and reported in presenting data.

(f). WITHSTAND TESTS

To provide a suitable terminology and facilitate testing procedure for withstand tests, the following definitions are suggested.

Withstand Voltage (for an impulse). The withstand voltage of a test specimen under an impulse of any given wave shape, polarity, and amplitude, which does not cause disruptive discharge on the test specimen, is the crest value attained by that impulse.

Critical Withstand Voltage (for an impulse). The critical withstand voltage of a test specimen under an impulse of any given wave shape and polarity is the crest value of that impulse when its amplitude is adjusted to be just below disruptive discharge on the test specimen.

Figure 3. The series of impulse waves illustrates the terminology and definitions associated with impulse voltage testing

Rated Withstand Voltage[*] *(for an impulse)*. The rated withstand test voltage of a test specimen is the crest value of an impulse of given wave shape and polarity, to be applied under specified conditions without disruptive discharge on the test specimen.

These definitions are illustrated in figure 3.

(g). Deviations in Test Data

For positive-polarity critical withstand and critical flashover voltage measurements, the value obtained in an individual test in any laboratory should be within eight per cent of available standardized values, which are average values or levels obtained on similar apparatus from tests made in a number of laboratories. Negative-wave flashovers are inherently more erratic than positive-wave flashovers, with more chance of this deviation being exceeded. In front-of-wave and volt-time curve testing somewhat greater discrepancies may be expected. This eight per cent deviation was derived from intercomparison of laboratory results and is not to be considered as a tolerance in acceptance tests.

III—Progress Report and Additional Recommendations

(a). Wet Flashover Tests for Insulators and Bushings

This problem is concerned principally with present differences in recommended precipitations and water resistances, wherein the Insulator Standards No. 41 calls for 0.2 inch per minute and a water resistance of from 15,200 to 20,300 ohms per centimeter cube, and Oil Circuit Breaker Standards No. 19 calls for 0.1 inch per minute with a water resistivity of 12,000 ohms per centimeter cube.

The committee examined submitted data, sponsored tests in several laboratories, and studied the question in considerable detail deciding finally that a single standard of precipitation rate should be used and proposed 0.2 inch per minute. A resistance of 15,200 to 20,300 ohms per cm cube (6,000 to 8,000 ohms per inch cube) is also proposed. It was found easier to control the precipitation when the higher rate was used. As far as natural rain conditions are concerned, there appears to be no preference between 0.1 and 0.2 inch per minute. The range of 6,000 to 8,000 ohms per inch cube resistivity involves a correction on one type of apparatus from 0.98 to 1.02. The correction may be disregarded when tests are made within this range of resistivity. Tests may be made outside this range of resistivity provided recognized resistivity correction factors are available. In such cases the resistivity correction factors should be specified in the standards applying to each particular type of apparatus.

Attention was also given to details of wet test arrangements and the following recommended.

1. A 45-degree directional angle for the spray
2. A one-minute wetting before voltage application
3. A pressure range for the water of 35 to 60 pounds
4. All precipitation measurements taken with the test specimen in place
5. A 6-inch to 12-inch diameter measuring vessel
6. Precipitation measured in three places and a variation of from 0.24 to 0.16 inch per minute allowed throughout the string length
7. The voltage applied at a rate requiring at least ten seconds to flashover

The committee recommendations are being considered for a revision of the insulator test standard which is now in process of preparation by the AIEE.

(b). Flashover of Switch and Bus Insulators

Data submitted by several laboratories on outdoor switch and bus insulators have been assembled and are being prepared for submission to the joint committee.

(c). Critical (Minimum) Flashover Voltages for an Impulse

In response to requests from several sources, this committee took action on the use of the word "minimum" in the definition of this quantity as it now appears in ASA Definition Standards 35.90.125. The committee considered a great number of substitutes and finally reached agreement on the use of "critical flashover voltage for an impulse". This term is therefore recommended for immediate use and for substitution in the ASA definitions. The following definition is also recommended:

"The critical flashover voltage of a test specimen under an impulse of given wave shape and polarity is the crest value of that impulse when its amplitude is adjusted to cause flashover on 50 per cent of the applications."

(d). Impulse Volt-Time Curves

In an effort to extend the co-ordination between laboratories on impulse tests obtained on rod gaps and insulators for the critical flashover voltage, volt-time curves from several laboratories on rod gaps, with the 1.5x40 wave, back to two microseconds have been compared. A wide disagreement which increased as the times became shorter was discovered. This disagreement reached ±20 per cent from the average of the laboratory curves for a single test at two microseconds. The disagreement has been shown to be partly caused by wave-shape differences particularly on the front. It has, therefore, been necessary to consider the basic problem of accurate control of impulse wave shapes. Additional tests and exchange of data are on schedule.

(e). Front of Wave Testing

This subject has been given attention by the committee and again differences between laboratories immediately involved consideration of means of production and accurate measurement of wave fronts. The problems here overlap those for item *d* above, "Impulse Volt-Time Curves," involving still more difficult problems of short-time testing.

---

[*] Note: When rated withstand test voltages are specified definite test procedure for demonstration purposes should also be specified. In behalf of uniformity it is urged that where possible the procedure recommended in sections II and III of this paper be adopted.

(f). IMPULSE WITHSTAND TESTS

The committee was requested to consider methods of making withstand tests and accordingly has exchanged information pertaining to definitions, test methods, and values concerned. Active exchange of data is continuing and a test procedure is suggested for cases where other standards do not apply. The specific test should be covered in each apparatus standard but it is recommended that this suggested procedure be adopted where possible.

Specifications for Rated Withstand Impulse Tests

1. *Purpose of Rated Withstand Tests.* Withstand tests are made to determine that dielectrics will be capable of withstanding the rated withstand test voltage without a disruptive discharge on the test specimen.

(*a*). For insulator types on which disruptive discharge takes the form of a flashover in air, the rated withstand test voltage is given for standard atmospheric conditions and the test voltage to be applied shall be adjusted as outlined in paragraph 5.

(*b*). For insulator types in which disruptive discharge occurs only as a breakdown of the solid or liquid dielectric, atmospheric corrections are not applied.

2. *Specimen Mounting.* The specimen shall be mounted for test in accordance with the requirements of the apparatus code applying to the specimen (for example, for bus insulators NEMA Publication 35-28 for 60-cycle flashover tests or new AIEE Standards No. 41 when accepted).

3. *Impulse Wave Shape and Polarity.* The wave shape, tolerances, and polarity shall be as specified by the apparatus code applying to the specimen. In general, the polarity shall be that which produces the lower critical withstand voltage on the specimen.

4. *Voltage Measurement.* The amplitude of the applied impulse waves shall be measured by the methods approved in the latest revision of AIEE Standards No. 4.

5. *Correction for Atmospheric Conditions.* For the conditions indicated in 1*a*, the rated withstand voltage shall be corrected with air density and humidity correction factors applicable to the test specimen such that:

$$V = RWV \times \frac{D}{H}$$

where

V = amplitude in kilovolts of the test wave
RWV = rated withstand voltage
D = relative air density
H = humidity correction factor applying to the test specimen

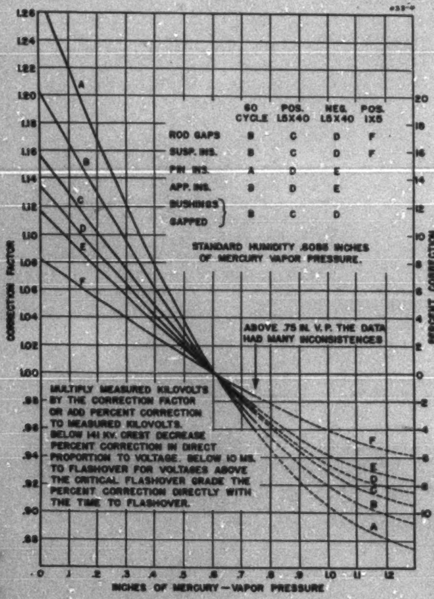

Figure 4. Humidity correction factors for flashover voltages of gaps, insulators, and bushings, based on average data from several laboratories

6. *Method of Test.* Three consecutive impulses shall be applied to the test specimen. The crest voltage of each shall not be less than the rated withstand voltage properly corrected (sections 1 and 5). If a disruptive discharge does not occur, the specimen shall be considered as having met the test.

If two or three of the applied impulse waves cause disruptive discharge, the test specimen shall be considered as having failed the test. If one of the applied impulses cause disruptive discharge,* three additional impulses shall be applied. If disruptive discharge does not occur, the specimen shall be considered as having met the test.

(g). SPHERE GAP AND CATHODE-RAY OSCILLOGRAPH MEASUREMENT COMPARISONS

Several laboratories have submitted comparative data on sphere-gap and cathode-ray-oscillograph measurements of crest voltages based on the criterion for measurement accuracy recommended in AIEE Standards No. 4 (revision of December 1937). Agreement is well within the five per cent stipulated in all cases and there appears to be no tendency for either method to give consistently higher values than the other.

(h). INTERNATIONAL ELECTROTECHNICAL COMMISSION PUBLICATION No. 60; GENERAL SPECIFICATIONS FOR IMPULSE VOLTAGE TESTING

Committee consideration has been given to this standard with the point in view of judging the value of such a general standard for equipment not now covered in particular apparatus or materials recommendations or codes. In the United States the trend to date has been to include all impulse testing recommendations in three places as follows:

1. All definitions of terms in the American Standards Association definitions.
2. All recommendations on measurements in AIEE Standards No. 4, Measurement of Test Voltage in Dielectric Tests.
3. All recommendations as to waves to be applied and circumstances peculiar to their application to be included in the particular apparatus or material codes.

This trend has been a healthy one and, rather than develop a new general standard, it is suggested that section II of this paper be used as an appendix to existing standards.

(i). CORRECTION FACTORS

Attention has been given wherever flashover results were being considered, to necessary corrections for relative air density and humidity. In the previous

---

* For solid dielectrics disruptive discharge results in permanent damage and the ruptured dielectric must be replaced.

Table I

Time to Flashover	Measured Kilovolts	Relative Air Density, Divide by	Humidity, Multiply by	Corrected Kilovolts
5	108	0.95	1.077	122
4	108	0.95	1.077	122
3	113	0.95	1.023	122
2	126	0.95	1.015	135
1	158	0.95	1.007	168
0.5	208	0.95	1.004	220

report of the committee humidity correction factors for 60-cycle and positive-wave impulse flashover of rod gap and suspension line insulators were submittted. Since then this work has been extended.

The dielectric strength of air is affected by its temperature and pressure. Also flashover voltages for nonhomogeneous electric fields vary with the absolute humidity of the air. Consequently, the following standard air conditions have been adopted:

Temperature	25 deg C (77 deg F)
Barometric pressure	760 mm (29.92 in.)
Humidity (vapor pressure)	15.45 mm (0.6085 in.)

Correction factors have been established and flashover voltages should be referred to standard air conditions. Similarly, in withstand tests, where air insulation is involved, corrections must be made for the air conditions at the time of the test. Where tests are made at high altitudes the barometric pressure correction automatically compensates for altitude.

1. *Relative Air Density.* The temperature and pressure are combined into one unit called relative air density, which is unity at 25 degrees centigrade and 760 millimeters pressure. The relative air density for any other condition is given by the formula

$$\text{r.a.d.} = \frac{0.392B}{273+T}$$

where

B is barometric reading in millimeters
T is temperature in degrees centigrade

The flashover voltage of disruptive discharges through air is corrected by using the same correction irrespective of frequency of the voltage causing flashover.

2. *Humidity.* The humidity correction varies for different types of apparatus and for different forms and polarities of test voltage. Corrections for a number of different conditions have been evaluated by actual tests over a wide range of absolute humidity and are given in figure 4. The corrections are given both as a correction factor (multiplier) and as a per cent correction (to be added). The latter is used in revising the amount of correction applied at low voltages and at short times. If, for a particular test, none of the standard correction curves applies, the one which most nearly approximates the conditions of wave form, polarity, and type of apparatus should be used.

CORRECTION PROCEDURE

(*a*). *Full Wave Test and Critical Flashover Voltages.* The measured test voltage is divided by the relative air density and multiplied by the humidity correction factor to give the equivalent voltage for standard air conditions. If the measured voltage is less than 141 kilovolts crest, the humidity per cent correction should be decreased in proportion for insulators and rod gaps.

$$H^1 = H\frac{\text{kv}}{141}$$

where H is the per cent correction from figure 4. The humidity correction factor is then $\frac{100+H^1}{100}$.

(*b*). *Front-of-Wave Tests and Volt-Time Curve Voltages.* In correcting volt-time curves to standard air conditions the following standard procedure should be followed:

1. Use the full relative air-density correction at all points on the volt-time curve. In practice, divide voltage values by the relative air density, which corrects to standard temperature and barometric pressure.

2. Use the humidity correction factors for different waves and apparatus, as given in figure 4.

(*a*). When the critical flashover voltage is less than 141 kv crest, grade the per cent correction directly with the voltage.

(*b*). For times to flashover less than ten microseconds, when the corresponding voltage value exceeds the critical flashover voltage, grade the per cent correction directly with the time to flashover.

In practice, multiply the critical flashover voltage values and all voltage values for times greater than ten microseconds by the humidity correction factor. For voltages exceeding the critical flashover voltage at times less than ten microseconds multiply the humidity per cent correction by a factor equal to the corresponding time to flashover divided by ten. The humidity correction factor used as a multiplier for short times then becomes 100, plus this reduced per cent correction divided by 100. When the transition point is considerably less than ten microseconds, judgment is necessary to maintain a smooth curve. When the critical flashover voltage is less than 141 kv crest, decrease the per cent correction in direct proportion to the voltage.

EXAMPLE

Assume the following volt-time curve for a 1.5x40 positive wave obtained on a rod gap at relative air density 0.95 and at a vapor pressure of 0.2 inch.

Time to Flashover (Microseconds)	Kilovolts
5	108
4	108
3	113
2	126
1	158
0.5	208

For a rod gap at 0.2 inch humidity, the correction factor is 1.101 or the per cent correction is 10.1 from figure 4.

(*a*). Correct for a voltage below 141 kv. For a critical flashover voltage of 108 the per cent correction becomes $108 \times 10.1/141 = 7.7$

(*b*). Correct for the time to flashover. At two microseconds the per cent correction is $2 \times 7.7/10 = 1.54$ or the correction factor is 1.0154. Similarly for times less than four microseconds in this case. The corrections for the curve are then as shown in table I.

The corrected kilovolts give the volt-time curve for standard air conditions.

All corrections given are subject to revision from time to time, as more exact test data become available.

Discussion

Discussion will be found in the 1940 annual TRANSACTIONS volume and in the 1940 "Transactions Supplement" to ELECTRICAL ENGINEERING.

Transient Starting Torques in Induction Motors

A. M. WAHL
Member ASME

L. A. KILGORE
MEMBER AIEE

Synopsis: A transient fundamental-frequency torque is shown to occur in the starting of all induction motors. For full-voltage starting on a general-purpose squirrel-cage motor, this torque may be as high as two or three times the pull-out torque. A consideration of such torques is particularly advisable for cases where induction motors are started and stopped frequently or continuously, since under such conditions mechanical failure of the motor or associated parts, gearing, couplings, etc., may occur if the stresses exceed the endurance limit of the material.

A method of analysis is given for calculating the transient electrical torques acting in the case of a locked rotor; the results obtained by means of this analysis are compared with test data obtained on a special locked-rotor test setup. A method is also given for calculating shaft torque from the electrical torque in the usual application. Test results also indicate that this method is satisfactory for practical use.

FOR many years engineers have used the average starting torque and pull-out torques of induction motors as the basis for mechanical design of shafts and couplings, not always realizing that high alternating torques existed at the moment of starting. So far as the authors are aware no one has published any practical analysis, or even a discussion of this problem.

The analysis and tests given in this paper show that when a motor is thrown on the line by the sudden closing of a switch, the contacts of which close simultaneously, a fundamental-frequency electrical torque which may be several times the pull-out torque, will be developed for the first few cycles. If the closing of the switch contacts of the several phases is not simultaneous, this alternating torque may be higher, and in the worst case of 90 electrical degrees lag, about 40 per cent higher alternating torques will exist.

The actual shaft and coupling torque will depend on the flexibility of the shaft and coupling and the inertia of the load and the motor. It is apparent that if the natural frequency of the mechanical system consisting of rotor, coupling, and load happens to be quite near the current supply frequency, the peak shaft torques may even exceed the electrical torque due to the resonance effect, particularly for high load inertias. Also, if the coupling has backlash or a nonlinear torque-angle characteristic, an increase in torque may be had due to impact effects. Where the driven-load inertia is of the same order of magnitude or smaller than the motor inertia, a reduction in shaft torque is to be expected.

The fact that trouble from this source has been encountered only in exceptional instances may probably be explained as follows: (1) Usually the torsional natural frequency of the system is well below the current supply frequency so that most of the alternating torque is absorbed by the inertia of the rotor and is not transmitted to the shaft; (2) in most applications, starts and stops are relatively few so that a fatigue condition due to repeated loadings does not exist. Consequently, for such conditions, transient torques several times the endurance limit for indefinitely repeated loading may be absorbed without harm. Another way of explaining this is that the endurance curve for the shaft material (with stress concentration present) rises steeply as the number of cycles of repeated stress is reduced; (3) ample safety factors in shaft design based on experience are normally used; and (4) in most applications, the driven-load inertia is of the same order of magnitude or smaller than the motor inertia.

The mathematical analysis is carried out for the case of the locked rotor and yields the maximum torque which will be obtained at full voltage. For the case of reduced-voltage starting with an autotransformer or star-delta connection some flux may remain in the motor at the instant full voltage is applied with the result that even higher torques may occur. These latter conditions are, however, not considered in the present paper.

Electrical Torques

Before attempting a mathematical analysis of the problem, it is desirable to develop a physical picture of what is going on inside the machine under these transient conditions. It is simpler to think in terms of a two-phase machine, since the two windings are in space quadrature and have no mutual inductance. It will be shown in the appendix that the three-phase currents of a three-phase machine can be resolved into components acting on two quadrature axes (α and β).

In dealing with the transient torques in a machine, probably the most useful form of analysis is based on the difference in the products of fundamental current on each axis and fundamental air-gap flux on the axis in quadrature. In per unit notation[1]

$$T = i_{1\alpha} B_\beta - i_{1\beta} B_\alpha$$

or if the magnetizing current i_m on each axis is expressed in per unit notation, *the unit value being the current required to produce a flux sufficient to induce rated voltage at no load*, then:

$$T = i_{1\alpha} i_{m\beta} - i_{1\beta} i_{m\alpha} \qquad (1)$$

The sudden application of an alternating voltage to a reactive circuit will produce a transient asymmetrical flux and current depending on the point on the voltage wave at which the switch is closed.

The fundamental-frequency transient torque results from the reaction of the asymmetrical flux on one axis with the

Paper 40-100, recommended by the AIEE committee on electrical machinery, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted October 6, 1939; made available for preprinting April 22, 1940.

A. M. Wahl and L. A. Kilgore are with Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

The authors wish to express their appreciation to E. C. Whitney for his assistance in carrying out the analysis for electrical torques developed in this paper.

[1] For all numbered references, see list at end of paper.

alternating current on the other, and also to the reaction of the asymmetrical current on one axis acting on the alternating flux in the other. The asymmetrical flux and the associated fundamental torque decay slowly, since these depend on the magnetizing inductance. The asymmetrical current and its associated fundamental torque decay rapidly since these depend on the leakage inductances. The torque components due to asymmetrical current and to asymmetrical flux are initially equal and of opposite sign.

The mathematical analysis is given in appendix *B* for the case of a locked rotor. The actual case of the machine coming up to speed becomes much more involved. However, the peak of this alternating shaft torque (except where exact resonance is approached) comes within the first few cycles and in this time the rotor will not have attained more than a few per cent speed and the effects of rotation on the transient currents and flux are negligible.

The results of this analysis of transient locked rotor torques are given in equation 11 in terms of the starting torque and locked power factor, for the case of simultaneous application of voltage to all phases.

For small machines, or larger high-torque machines, where the locked power factor ($\cos\phi$) is not less than 0.3, the component of alternating torque due to the asymmetrical current dies out so rapidly as to be negligible and the peak electrical torque may be obtained by neglecting the terms involving λ_2, which gives:

$$T_{1m}=T_s\left(1+\frac{1}{\cos\phi}\right) \qquad (2)$$

For a large motor with low locked power factor the component due to the asymmetrical current decays more slowly. The resultant alternating torque starts at zero and builds up to a maximum in a few cycles, and the peak electrical torque will still be approximately that given by equation 2.

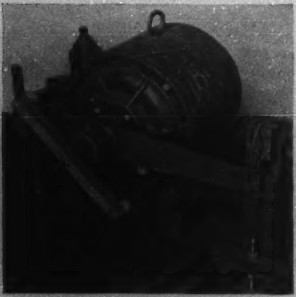

Figure 1. Test setup for measuring electrical torques

These equations apply only when there is simultaneous voltage application on all three phases. Such a condition is often difficult to obtain with actual switches or contactors. For this reason a second analysis was carried out by assuming that the switch was closed on one phase of the equivalent two-phase machine 90 electrical degrees (or 0.004 second at 60 cycles) later than on the other phase. On the three-phase machine this would mean that the third phase was closed 90 electrical degrees after the closure of the second phase. The results of this analysis are given in equation 12. Again neglecting terms involving λ_2 the peak electrical torque becomes:

$$T_{1m}=T_s\left(1+\frac{\sqrt{2}}{\cos\phi}\right) \qquad (3)$$

Values of peak torque found for such conditions are around 20 to 40 per cent higher than those obtained on the assumption of simultaneous voltage application.

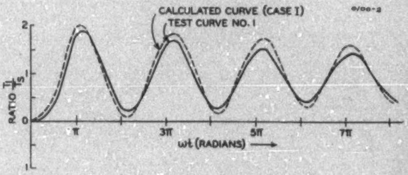

Figure 2. Comparison of test and calculated torque curves for typical high-torque induction motor

A physical explanation of the increased torque due to closing the last phase 90 degrees later may be had, by considering that this may result in maximum asymmetrical flux in each of the two axes which gives a resultant asymmetrical flux $\sqrt{2}$ times the maximum value on one axis.

Tests to Determine Electrical Torques

In order to check up on the theoretical work, a special locked-rotor test arrangement (figure 1) so designed as to record transient torques was used. Essentially, it consists of an arm attached to the motor shaft and held at its end by a thin tool-steel bar. Under the action of pulsating torques, this tool-steel bar is stretched or contracted, these transient movements being recorded on an oscillograph by means of a magnetic strain gauge.[3] By using a tool-steel bar, a fairly high natural frequency, relative to the current supply frequency, was obtained. The relation between rotor torque and oscillograph-beam deflection is established by a static calibration.

In figure 2 a typical curve of transient starting torque obtained on a high-resistance induction motor is shown by the full lines. It may be seen that this consists essentially of a pulsating component at the current supply frequency which dies out after a time. For comparison, a calculated curve obtained from equation 11 is also shown.

A summary of ratios of maximum torque T_m to nominal starting torque T_s obtained on various rotors at different frequencies (so that $\cos\phi$ varied from about 0.6 to 0.95) is shown in figure 3. It may be seen that while there is considerable scatter in the results, most of the test points occur between the limits of the curves defined by the approximate equations 2 and 3, with the latter equation yielding an approximation to the upper limit.

Transient Shaft Torques

GENERAL METHOD—LINEAR COUPLINGS

The preceding discussion has been primarily concerned with the transient electrical torques acting on the rotor at the instant of starting. In most cases, however, the designer is mainly concerned with the transient shaft torques, since on these depends the design of the mechanical parts. As mentioned before, these shaft torques depend not only on the electrical torque, but also on the other characteristics of the drive including rotor and load inertias, flexibility of shaft-coupling system, and in certain cases, the shape of the torque-angle characteristic of the coupling.

In many cases of practical interest, an induction motor is coupled to a heavy inertia load by means of a flexible coupling. An example of such construction is the roll-table drive used in continuous strip mills. In such cases the system may usually be represented for purposes of analysis by a single degree-of-freedom system consisting of a mass, representing the motor, connected by a spring, representing the coupling and shaft flexibility, to a rigid body. This analysis will hold approximately where the equivalent driven-load inertia is large compared to that of the motor. As will be shown later, the results for this case may also be used when the load inertia is finite.

If we neglect damping, the known differential equation of motion for such a system, assuming a coupling with a linear torque-angle characteristic is

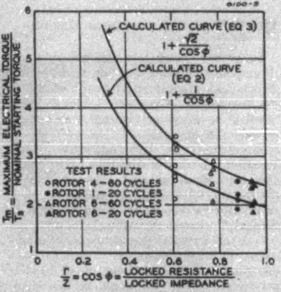

Figure 3. Comparison of test and calculated values of ratios between peak electrical torque and starting torque

$$I_m \frac{d^2\theta}{dt^2}+k\theta=F(t) \qquad (4)$$

The shaft torque may be determined by introducing $F(t)$ as given by equations 11 or 12 into equation 4 and integrating, the integration constants being determined from the initial conditions which require that when $t=0$, $\theta=0$, and $d\theta/dt=0$. Because of the rather complicated expression for $F(t)$, such an integration becomes very laborious and for this reason the following alternative method was used.

By using the principle of superposition, it may be shown that if damping is neglected, the angular displacement for the single degree of freedom system under consideration is given by:[3]

$$\theta=\frac{1}{\omega_n}\int^{t_1}\frac{F(t)}{I_m}\sin\ \omega_n(t_1-t)dt \qquad (5)$$

Application to High-Resistance Rotors

Unless the damping is unusually high, it is justifiable where high-resistance rotors are involved to neglect damping in practical systems where the natural frequency of the system is much less than the current supply frequency since in such cases the peak torque will occur within the first cycle of oscillation at the natural frequency.*

Assuming as before that the magnetizing reactance is very large compared to the rotor or stator resistance, the decrement factor λ_1, will be small compared to ω. Hence, the term $\epsilon^{-\lambda_1 t}$ may be taken as unity in the expression for $F(t)$, since during the first few cycles of applied voltage during which the maximum shaft torque occurs, this term will differ but little from unity. With this simplification, by integrating equation 5 the expression for shaft torque takes the form:

$$T=T_s\{1+\beta_1\epsilon^{-\lambda_2 t}+\beta_2\epsilon^{-\lambda_2 t}\sin\ (\omega t+\gamma_2)+\beta_3\times \sin\ (\omega_n t+\gamma_3)+\beta_4\sin\ (\omega t+\gamma_4)\} \qquad (6)$$

where β_1, β_2, β_3, β_4, γ_2, γ_3, γ_4, depend on ω/ω_n and ϕ.

For typical high-resistance rotors ($\cos\phi>0.3$), it may be assumed that the term $\epsilon^{-\lambda_2 t}$ dies out very rapidly during the first cycle of applied voltage, so that it may be neglected as far as any contribution to the peak torque is concerned. (The results, however, should not be applied when low-resistance rotors are being considered.) In addition, in practical cases where ω_n is not over say $\omega/2$, it may be assumed as a first approximation, that the phase angles γ_3 and γ_4 are such that the torque components β_3 and β_4 add directly. (This will yield results somewhat on the safe side, the closeness of the approximation being greater for smaller ratios of ω_n/ω.) With these simplifications, the peak shaft torque (for high-resistance rotors) becomes:

$$T_m=T_s\{1+\beta_3+\beta_4\} \qquad (7)$$

Values of the ratio T_m/T_s obtained by using this method for various values of $\cos\phi$ are plotted in figure 4 for simultaneous voltage application on both axes and in figure 5 for voltage application on the β axis 90 degrees later than on the α axis. It may be seen that the latter assumption yields definitely higher shaft torques. It should also be noted that peak transient shaft torques as high as four to five times the nominal starting torque may occur for cases where $\cos\phi=0.5$ and $\omega_n/\omega=0.5$. In utilizing these curves, it should be borne in mind that because of the assumptions made, the ratios T_m/T_s may be somewhat overestimated for the larger ratios of ω_n/ω.

An alternative method for obtaining an approximate solution is to take $\epsilon^{-\lambda_2 t}=0$ and $\epsilon^{-\lambda_1 t}=1$, as before, in the expressions for torque given by equation 11 or 12. These approximate expressions are then substituted for $F(t)$ in the differential equation (4) and the integration carried out. Assuming as before that the torque components at the natural frequency and at the current supply frequency add directly, peak torques somewhat lower than those given by the curves of figures 4 and 5 are obtained.

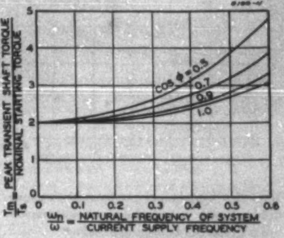

Figure 4. Variation of maximum shaft torque with torsional natural frequency—simultaneous voltage application

Infinite load inertia and simultaneous voltage application in all phases assumed

The previous discussion deals only with the case where the equivalent load inertia is infinite compared to that of the motor rotor. Where this is not the case, that is, if the load inertia is of the same order of magnitude as the motor inertia (a condition which frequently occurs in practice), a comparison of the differential equations for the two cases shows that the curves of figures 4 and 5 may still be used provided that the natural frequency is determined by using an equivalent moment of inertia

$$I_e=\frac{I_m I_r}{I_m+I_r}$$

instead of I_m, and provided that the peak torque, thus found, is reduced in the ratio $I_r/(I_m+I_r)$.

Where the torque-angle characteristic of the coupling is nonlinear (as it is in many practical couplings) the differential equation (equation 4) will still apply if the constant k is replaced by a function $f(\theta)$ which represents the torque-angle characteristic of the coupling. Usually an analytical solution of this

---

* When operating with a natural frequency not far from the supply frequency, damping should be considered for an accurate solution.

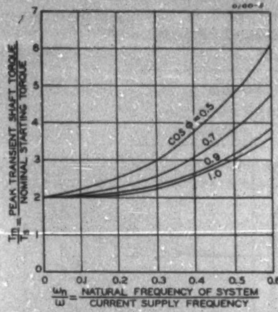

Figure 5. Variation of maximum shaft torque with torsional natural frequency—nonsimultaneous voltage application

Infinite load inertia and voltage application β axis 90 electrical degrees later than on α axis

modified equation is impractical and in such cases a numerical solution* has given good results when compared with actual test values.

The peak shaft torques obtained by using the methods of calculation outlined herein have been compared with the results of actual torque measurements on a typical high-resistance induction motor coupled to a heavy inertia load by means of a flexible coupling. The torques were measured by means of a magnetic strain gauge so mounted as to measure shaft twist, the results being recorded on an oscillograph. The tests were carried out by using a number of different makes of flexible couplings. Although a complete discussion of these results is beyond the scope of the present paper, it may be mentioned that the results indicate that the methods of calculation developed herein for high-resistance rotors are satisfactory for practical application.

LOW-RESISTANCE ROTORS

For low-resistance rotors the $\epsilon^{-\lambda_2 t}$ term in equations 11 or 12 of appendix *B* cannot be neglected. In the first instant, $\epsilon^{-\lambda_2 t}$ is unity and the two components of alternating torque are found to cancel out. After a few cycles $\epsilon^{-\lambda_2 t}$ has decreased considerably and the alternating electrical torque approaches the value obtained from equations 11 and 12 by putting $\lambda_2=0$. Because the alternating torque builds up slowly an approximation to the peak torque should be had by adding directly (1) the shaft torque component at the natural frequency (produced by the impact effect of the average electrical torque applied in the first instant after starting) and (2) the torque component at fundamental frequency due to the alternating electrical torque. Where the load inertia is large, the first of these components will be about twice the average electrical torque in the first instant after starting. Where the ratio ω_n/ω is not low, it would appear that a rough estimate of this average torque could be obtained from equations 11 and 12 by taking $\epsilon^{-\lambda_2 t}$ as unity and neglecting the trigonometric terms. This gives an average electrical torque of $2T_s$ and $(1+\pi/2)T_s$ for the simultaneous and nonsimultaneous cases respectively, with resulting peak shaft torques of $4T_s$ and $(2+\pi)T_s$ due to the impact effect for the two cases. It should be noted that these values may be somewhat too high for the lower values of ω_n/ω and for very low values (say 0.1 or less) the peak impact torque may be taken as $2T_s$. To this must be added the fundamental-frequency shaft torque component due to the alternating electrical torque which is $\pm 1/(\omega^2/\omega_n^2-1)$ cos ϕ or $\pm\sqrt{2}/(\omega^2/\div\omega_n^2-1)\cos\phi$ for the simultaneous and nonsimultaneous cases, respectively, the negative sign being used if $\omega<\omega_n$. For a more accurate solution in any particular case equations 11 or 12 may be taken as the expressions for $F(t)$ in equation 5 and the integration carried out. The fact that mechanical damping is neglected when figuring the torques by these methods means that the calculated values of shaft torque may be somewhat too high particularly where the natural frequency is not far from the current supply frequency. Where the load inertia is not large compared to the motor inertia, these values should also be reduced in the ratio $I_r/(I_m+I_r)$ as discussed previously.

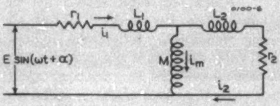

Figure 6. Equivalent circuit used in analysis

Conclusions

1. All induction motors started by sudden application of voltage will have transient fundamental-frequency electrical torques. If started at full voltage the peak electrical torque may be two times the pull-out torque or more.

2. The transient electrical torques can be calculated by equations 11 and 12. For a high-torque motor the peak electrical torque is given approximately by equations 3 and 4.

3. The test results (figure 3) show that the method of analysis is sufficiently accurate.

4. Mechanical torques for the common case where the torsional natural frequency of the mechanical system is well below the supply frequency are given by curves of figures 4 and 5 for high-torque motors. A method is also outlined for motors with low locked power factor.

Appendix A

The Equivalent Two-Phase Machine

Park[4] has shown how the currents of a three-phase machine may be resolved into direct- and quadrature-axis components on the two axes of the rotor. More recently Stanley[5] has given a somewhat more general analysis by resolving the three-phase currents along any two quadrature axes. Examination of the resulting equations of this method shows that they are exactly the same as for a simple two-phase machine, except for zero-sequence currents (that is, current flowing in the neutral).

One can arrive at this same conclusion by simple physical reasoning. The current in one phase may be thought of as dividing between the other two phases and this will be taken as one of the two-phase components. The second two-phase component will be the difference in the currents of the other two phases. So long as there are no neutral currents, the resultants of these two-phase components will be equal to the real three-phase current in any phase.

In order to establish the relation between the equivalent two-phase components, take *I* and *E* as the line currents and phase-to-neutral voltage of the three-phase machine. Then *I* and $3/2E$ are the current and voltage of the first phase of the equivalent two-phase machine, and $\sqrt{3}/2$ and $\sqrt{3}E$ are the current and voltage of the second phase. Either of these two phases could be used as the reference, but it is more convenient to use the first. For this case the equivalent two-phase current is the same as the three-phase current, but the two-phase voltage and the inductance and resistance values will be taken as 3/2 times the three-phase line-to-neutral values.

The locked two-phase machine consists essentially of two independent transformers and the usual transformer equivalent circuit (figure 6) can be used accurately to represent current and voltage relations on each axis. The inductance coefficients L_1 and L_2 are the leakage inductances of the primary and secondary, and are numerically equal to the ohms reactance divided by $2\pi f$. *M* is the magnetizing inductance.

The secondary constants L_2 and r_2 are converted to the primary as is customary in all induction-motor calculations. Actually the secondary reactance and resistance are in most cases affected by eddy currents. The locked values of these constants will be used because they are correct for the fundamental-frequency currents, and the error is only in the decrement.

* See Timoshenko, reference 3, page 126, for an example of such a solution applied to a similar case.

Appendix B

Calculation of Transient Electrical Torques

In line with the discussion of appendix A the induction-motor winding is assumed divided into α and β components with axes at 90 degrees. Each component is represented by the equivalent circuit of figure 6. The voltage applied to the circuit is given in the general form $E \sin(\omega t+\alpha)$ and the parameter α may be so chosen for each axis that the voltages acting on the α and β axes will be 90 degrees apart. Referring to figure 6, assuming constant values of L_1, L_2, and M, the following differential equations hold:

$$(r_1+pL_1)i_1+pMi_m=E\sin(\omega t+\alpha)$$

$$(r_1+pL_1)i_1+(r_2+pL_2)i_2=E\sin(\omega t+\alpha) \qquad (8)$$

$$i_1=i_2+i_m$$

The solution of these equations may be obtained either by using operational methods or by using the ordinary methods of solving differential equations, but the resulting expressions become rather cumbersome if all the terms are included. However, a simplification is possible since in practical motors the stator and rotor leakage inductances L_1 and L_2 are very small in comparison with the mutual inductance M, and hence may be neglected in certain expressions.*

The following boundary conditions hold:

at time $t=0$, $i_1=0$, $i_m=0$

and since no current is present when $t=0$

$$L_1pi_1+Mpi_m=E\sin\alpha$$

$$L_2pi_2-Mpi_m=0$$

In this manner we find:

$$i_1=I'\{(\sin\phi\cos\alpha-\cos\phi\sin\alpha)\epsilon^{-\lambda_2 t}+\sin(\omega t+\alpha-\phi)\} \qquad (9)$$

$$i_m=I_m'[\epsilon^{-\lambda_1 t}\cos\alpha-\cos(\omega t+\alpha)] \qquad (10)$$

The instantaneous electrical torque is obtained from equation 1. Two cases are assumed as follows:

Case I. Simultaneous application of voltage to both axes.

Case II. Application of voltage to β axis 90 degrees later than α axis to simulate effect of bouncing of switch contacts or irregularity in voltage application.

In practice it will be found almost impossible to apply voltage to all three phases at exactly the same instant; on the other hand the assumption of a 90-degree phase difference between voltage application to the two axes probably represents a fairly severe condition.

Case I—Simultaneous Application of Voltage to Both Axes

In this case we use equations 9 and 10 taking $\alpha=0$ for the α axis and $\alpha=90$ degrees for β axis. Thus $i_{1\alpha}$ and $i_{m\alpha}$ are found from these equations by taking $\alpha=0$; $i_{1\beta}$ and $i_{m\beta}$ by taking $\alpha=90$ degrees. Using the expressions for $i_{1\alpha}$, $i_{m\alpha}$, $i_{1\beta}$, $i_{m\beta}$ thus found in (1) we obtain for the torque:

$$T_1=T_s\left\{1+\epsilon^{-\lambda_2 t}-\frac{\epsilon^{-\lambda_2 t}\cos(\omega t+\phi)+\epsilon^{-\lambda_1 t}\cos(\omega t-\phi)}{\cos\phi}\right\} \qquad (11)$$

Case II—Application of Voltage to β Axis 90° Later Than on α Axis to Simulate Effect of Bouncing of Contacts or Irregularity in Voltage Application

In this case we again use equations 9 and 10 and assume that the switch is thrown on the β axis 90 degrees later than on the α axis. Let t = time measured from instant switch is thrown on the α axis and t_1 = time measured from instant switch is thrown on the β axis; then

$$t=t_1+\frac{\pi}{2\omega}$$

On the α axis we take $\alpha=0$ and $t=t_1+\pi/2\omega$ in equations 9 and 10 and thus obtain expressions for $i_{1\alpha}$ and $i_{m\alpha}$ in terms of t_1. The currents $i_1\beta$ and $i_{m\beta}$ on the β axis will be obtained from the same equations in this case by taking $\alpha=180$ degrees and $t=t_1$ to take into account the fact that there is a phase difference of 90 degrees between the voltages and a lag of 90 degrees between the time the switch is thrown on the two axes. Using these values of $i_{1\alpha}$, $i_{m\alpha}$, $i_{1\beta}$, and $i_{m\beta}$ in equation 1 the following expression for the electrical torque T_2 is obtained in terms of the time t_1:

$$T_2=T_s\left\{1+\tan\phi\left[(1-c)\epsilon^{-\lambda_2 t_1}+(\sqrt{1+c^2})\epsilon^{-\lambda_2 t_1}\sin(\omega t_1+\alpha_1)\right]+\frac{\sqrt{2}}{\cos\phi}\epsilon^{-\lambda_1 t_1}\sin\left(\omega t_1-\phi-\frac{\pi}{4}\right)\right\} \qquad (12)$$

where

$c=\epsilon^{-\frac{\lambda_2\pi}{2\omega}}$ and $\alpha_1=\tan^{-1}c$.

Nomenclature

$\cos\phi=\dfrac{r}{\sqrt{x^2+r^2}}$ = locked power factor

E = maximum value of applied voltage per phase

$f(\theta)$ = function representing torque-angle characteristic of shaft-coupling system

i_1, i_2 = stator and rotor phase currents

i_m = magnetizing current per phase

$i_{1\alpha}$, $i_{m\alpha}$ = stator and magnetizing currents on α axis

$i_{1\beta}$, $i_{m\beta}$ = stator and magnetizing currents on β axis

I' = peak value of steady-state locked stator current

I_m' = peak value of steady-state magnetizing current with rotor locked

I_m, I_r = moments of inertia of motor and driven load respectively

$I_e=I_mI_r/(I_m+I_r)$ = equivalent moment of inertia of rotor-coupling-load system

k = spring constant of shaft-coupling system

L_1, L_2 = stator and rotor leakage inductances per phase

M = mutual or magnetizing inductance

$p=d/dt$ = derivative operator

r_1, r_2 = stator and rotor resistances per phase

$r=r_1+r_2$

T_1 = electrical torque assuming simultaneous voltage application on α and β axes

T_{1m} = maximum electrical torque assuming simultaneous voltage application

T_2 = electrical torque assuming voltage application on β axis 90 degrees later than on α axis

T_{2m} = maximum electrical torque assuming voltage application on β axis 90 degrees later than on α axis

T_m = peak shaft torque or electrical torque

T_s = nominal starting torque

T = shaft torque

t = time

$\omega=2\pi$ times frequency of applied voltage

$\omega_n=2\pi$ times natural frequency of system consisting of motor rotor, coupling, and load

$x=x_1+x_2$

x_1, x_2 = stator and rotor leakage reactances per phase

x_m = magnetizing reactance

λ_1, λ_2 = decrement factors. $\lambda_1=\dfrac{\omega r_1r_2}{x_mr}$; $\lambda_2=\dfrac{\omega r}{x}$

θ = angular twist of shaft-coupling system between motor and load

β_1, β_2, β_3, β_4 = transient shaft-torque components

γ_2, γ_3, γ_4 = phase angles of corresponding transient shaft-torque components

* An integration of these equations in which no terms were neglected has been carried out by E. H. Moss using numerical values for the constants M, L_1, and L_2 corresponding to an actual motor. This showed close agreement with the approximate method described.

A High-Speed Differential Relay for Generator Protection

W. K. SONNEMANN
ASSOCIATE AIEE

RECENT papers have shown that high-speed differential relaying is considerably complicated by the presence of the d-c transient in asymmetrical through fault currents. This is particularly true of generator differential relaying, since an asymmetrical fault near the terminals of a generator provides a more severe d-c transient than at any other point on the system. The effect of the d-c component is to produce a false differential current during a through fault because of dissimilar performance of the current transformers, even though they may nominally be duplicate. When this false differential current reaches tripping proportions with respect to the restraining current, even for as short a time as one cycle with a high-speed relay, the relay problem becomes one of properly discriminating between a false and a true differential current of tripping magnitude.

Means have been provided in the relay described in this paper to make the above discrimination. The solution has been worked out in accordance with two general principles. First, the principle of variable-ratio characteristics has been used. This principle was first described in a paper[1] presented at the 1939 winter convention, wherein it is shown that when the restraining current is large, corresponding to a heavy external fault, the sensitivity of the relay should be reduced to allow for greater shortcomings in current-transformer performance. Second, both theory and tests have shown that when current-transformer saturation occurs, the false differential current tends to be out of phase with the restraining current. Consequently, the new relay has been made less sensitive at the higher restraint values when the differential current is out of phase with the restraining current. The new relay is shown in figure 1, together with the necessary external transformer. The relay and transformer together form a complete three-phase unit.

Principle of Operation

In order to analyze the principle of operation of the relay, a simplified diagram, showing the essential parts for one phase only, is desirable. This is shown in figure 2. The main current transformers on each side of the generator are shown connected to terminals 1, 2, and 3 of the transformer element which feeds the relay. The principal currents from the secondaries of the current transformers in the leads of the generator flow only in the external transformer, as will be noted in the diagram. The transformer element develops auxiliary current and voltage quantities for actuation of the relay element shown in the bottom part of the diagram. The relay element has been shown very schematically. It is composed of a balanced-beam element wherein the contacts are restrained from closing by split-phase voltage windings acting on the rear end of the beam, while the operating-coil magnetic circuit acting on the front end of the beam tends to close the contacts. Inspection of the transformer element of this diagram will show that it consists of two transformer elements, both on the same magnetic circuit. Coils *A* and *B* on the center leg of the punchings form one of these transformers, which will be referred to as the sum coil transformer, wherein a voltage is developed in winding *B* in response to the restraining currents, I_1 and I_2. Since the voltage developed by winding *B* energizes split-phase restraining coils as shown, it is evident at once that the restraining force on the back end of the beam will never pass through zero.

A possible difference current, I_3, is shown flowing in the differential connection of the main current transformers in the diagram. In the transformer element, this current must flow through the two primary coils, C_1 and C_2, of the second transformer unit on the magnetic core, this unit being referred to as the difference coil transformer. The coils, D_1 and D_2, form the secondary windings of this second unit. They are connected in series to energize the operating coil of the relay element.

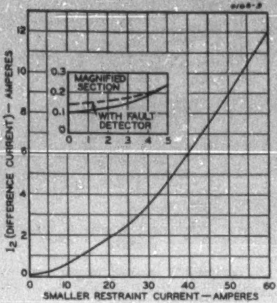

Figure 3. Typical operating characteristics of relay. Difference current, I_2, in phase with restraint current

Variable-Ratio Characteristics

Assuming in-phase currents, it will be seen from figure 2 that if the difference-coil current transformer is made to saturate to a greater extent at the higher currents than the sum-coil current transformer, and assuming linear relay characteristics, then it is obvious that a higher percentage of difference-coil current will be required to trip the relay contacts as the saturation of the difference-coil transformer is increased with respect to the sum-coil transformer. That is, as the restraint current is increased, the difference current to trip the relay will increase at a higher rate, thus resulting in the variable-ratio characteristic of figure 3. It will be noted from the curve that the minimum tripping current of the relay is 0.1 ampere in terms of the secondary, thus providing high sensitivity at no load on the machine. At 5 amperes restraint current, corresponding to full load, the difference current required to trip the relay is 0.25 ampere. This corresponds to a relay sensitivity of 5 per cent. From this point on, the variable-ratio characteristic of the relay is illustrated by the curve. For example, at 60 amperes restraint, a difference current to trip of 12 amperes represents 20 per cent unbalance. This indicates a decrease in sensitivity of the relay by a four-to-one range between normal and 12 times normal full-load current.

Phase-Angle Characteristics

Flux arrows have been drawn in the transformer element, figure 2, corresponding to the relative instantaneous direction of the currents, I_1, I_3, and I_2, as shown. The polarity of the connections of coils C_1, C_2, is such that ϕ_D, established by the difference current, I_2, flowing through coils, C_1 and C_2, circulates around the outer legs of the laminations. With symmetrical coil designs, there is no tendency for a portion of the flux, ϕ_D, to circulate through the middle leg of the transformer, since the two ends of this leg will be at the same magnetic potential with respect to ϕ_D. Thus, the flux, ϕ_D, established by the difference current, I_2, does not tend to establish directly a restraining-coil voltage, E_R, in coil B. The flux, ϕ_S, set up by the currents, I_1 and I_3, in coil A returning from top to bottom in the outer legs of the transformer as shown, has no tendency to induce operating-coil current in coils, D_1 and D_2, since, because of the polarity of connections of coils, D_1 and D_2, opposite voltages will be generated in these two coils by ϕ_S. From the above discussion, it is evident that if the magnetic material were of infinite permeability and never saturated regardless of the required flux density, the two transformer units, A/B and C_1C_2/D_1D_2 would have no effect upon each other and there would be no point to placing them both on the same magnetic structure. The fact that the magnetic material is not perfect, however, does introduce a mutual reaction between the two transformers, and this will be discussed.

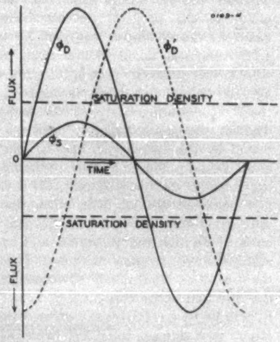

Figure 4. Flux waves in auxiliary current transformer

Assume that the currents I_1, I_3, and I_2, of figure 2 are associated with the flux waves of figure 4, these flux waves being required to generate sufficient voltage in the respective coils to circulate the currents, I_O and I_R, through the relay element. With I_2 in phase with I_1 and I_3, the power factor of the relay burden, both restraining and operating coils, may be so chosen that the fluxes, ϕ_S and ϕ_D, of figure 4 will be in phase as shown by the solid-line curves. If the quantities are so chosen, however, that the peak of the flux, ϕ_D, for the difference-current transformer, C_1C_2/D_1D_2, extends considerably into the zone of saturation, as shown in figure 4, then it will be noted that the peak flux, ϕ_S, for transformer A/B will be hard to obtain magnetically. That is, the return circuit for ϕ_S is the outer legs of the magnetic core in parallel, and these two outer legs are at that particular instant badly saturated by the difference transformer flux, ϕ_D. What this means is that a larger percentage of the sum-coil currents, I_1 and I_3, will go to magnetizing current, leaving a very small percentage to be transformed into restraining coil current, I_R, through the winding, B. (Casual inspection of figure 2 might indicate that the right-hand leg of the transformer punching might serve as a good return circuit for ϕ_S, since ϕ_S and ϕ_D are shown in opposite directions in this leg, thus reducing saturation and voiding the above argument. However, the argument is still valid, because at high saturation densities, there is not much difference between the amount of ampere turns required to reduce the flux density by a small increment and the amount of ampere turns to increase the flux density by the same small increment.) Thus, the solid-line flux, ϕ_S, of figure 4 is associated with a phase-angle condition in which it would be expected that the required difference current to trip the relay would be reduced because

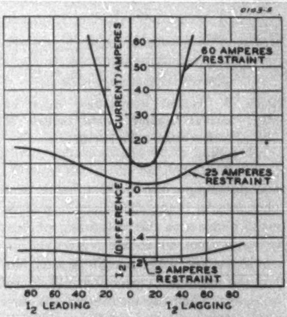

Figure 5. Typical phase-angle characteristics of relay

Phase angle in degrees of difference current with respect to smaller restraint current of a reduced efficiency of the sum-coil transformer. If now the phase angle of the difference-coil current, I_2, is changed by 90 degrees with respect to the restraining current, I_1 and I_3, so that the difference-coil flux, ϕ_D, is moved by 90 degrees lagging, as shown by the broken-line curve, ϕ_D', of figure 4, it will be noted that the peak of sum-coil flux, ϕ_S, occurs at the instant that the difference-coil flux is passing through zero. It would be expected that under this condition the sum-coil transformer would operate more efficiently than in the previously described case, since the peak of its flux, ϕ_S, is more easily obtained when its return circuit is not saturated. The above discussion indicates that since the difference-coil transformer, through its flux requirements, is caused to saturate the return circuit for the sum-coil transformer, and since this saturation effect varies throughout the cycle, then the mutual reaction between the two transformers is variable, depending upon the phase-angle relationship between the sum-coil currents and the difference-coil current. By suitably proportioning the power factor and magnitude of the restraining-coil and operating-coil burdens of the relay element in conjunction with the transformer design, it was possible to arrive at a design in which the combination is less sensitive to difference-coil currents when these difference-coil currents are substantially out of phase with the restraining-coil currents.

The phase-angle characteristics of the relay are illustrated in figure 5. The curve shows that at 60 amperes restraint, it is practically impossible to cause the relay to trip if the difference current is out of phase with the restraining current by more than 40 to 50 degrees. This provides a very large margin of safety in that the difference currents are likely to be highest when the restraining-coil current is the greatest, and they will also tend to be out of phase with the restraining-coil currents. At five amperes restraint, however, corresponding to full-load current, it should be noted that the phase-angle curve of the relay is substantially flat. This is desirable at load current, because there is no way of predicting just what the phase-angle relationship will be between a small internal fault current in a generator and the load current on the machine at the time.

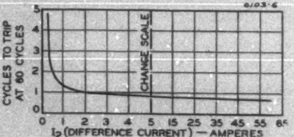

Figure 6. Typical current-time curve of relay. Smaller restraint current constant at five amperes (full load)

When considering the phase-angle curves, it should be remembered that those curves where the restraint current exceeds 5 amperes represent through short-circuit conditions. For this reason, there is no cause for alarm in the indication that, for example, a 40-ampere differential current at 60 degrees lagging would not trip the relay at 60 amperes restraint. It would be impossible to obtain an internal short-circuit of 40 amperes magnitude and maintain a through current of 60 amperes for an external fault. In other words, these curves, except for the 5-ampere restraint curve, apply only to through fault conditions, and are not applicable to internal fault conditions without proper interpretation of the effect of the sum-coil currents. For example, the 60-ampere restraint curve referred to was taken with a setup in which the sum-coil current directions agreed with those shown in figure 2, these representing an external fault. That is, the sum-coil ampere turns produced by the currents, I_1 and I_3, were additive and produced a positive restraining force on the relay element. If it is now assumed that a fault within the differential zone draws 60 amperes (secondary) through the generator, and an additional 60 amperes back-feed from the bus, it is immediately obvious that the direction of the two currents, I_1 and I_3, will be reversed with respect to each other, their ampere turns will cancel in the sum-coil transformer, and there will be no restraint. Hence, the curve does not apply. For another example, let it be assumed that for the same internal fault, the generator current, I_1, is 60 amperes, but that the back-feed current I_3 reversed, is increased to 180 amperes. Then 60 amperes in one-half of the sum coil winding will cancel the effect of 60 amperes of the 180 amperes in the other half, leaving a net effect of 120 amperes in half of the winding, equivalent in effect to 60 amperes flowing in one coil and out of the other, as shown in figure 2. In this case, then, the 60-ampere curve of figure 5 would apply, although it should be remembered that the difference-coil current would be definitely fixed as the sum of the 60- and 180-ampere currents. This sum could conceivably be somewhat out of phase with the net restraining-coil current, but not enough to affect positive relay operation. Referring back to the curve for 5 amperes restraint, figure 5, it is possible that a light internal fault might occur which would not disturb the normal through load current of 5 amperes to any great extent, hence, this curve is applicable for internal faults as stated.

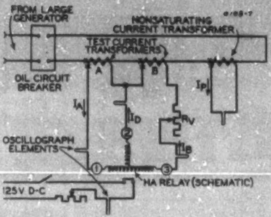

Figure 7. Schematic diagram of test connections

R_v represents a variable resistor used to produce more severe saturation in current transformer *B*

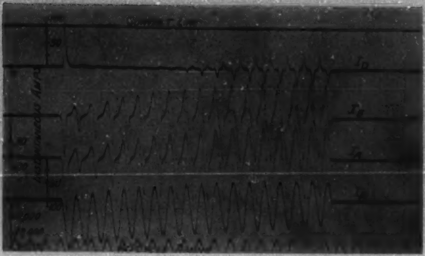
The time of operation of the relay is shown by the current-time curve of figure 6, wherein it is shown that the relay is a one-cycle relay.

Fault Detectors

The relay is provided with three small solenoid-type fault detectors, one for each of the elements, which may be used for those locations where the switchboard panel is subject to heavy jars or vibrations. At very light loads, the restraint occasioned by the load current may be negligible, and the extreme sensitivity of the differential element renders it subject to momentary closing of the contacts because of jars to the panel. In order to eliminate false tripping from this cause, the fault detectors are provided. Their coils are connected in parallel with the operating coils, and their contacts in series with the differential element contacts. Use of the fault detectors increases the minimum tripping current to 0.14 ampere, but has a negligible effect on the rest of the operating characteristics, figure 3.

Confirming Tests

Suitable tests have been made on the relay described. The essentials of the test connections are shown in figure 7. A large generator was used, so that d-c time constants up to $T_a=0.14$ were obtained. The resistor, R_v, of figure 7 was used to increase the burden on test transformer *B* so that the two transformers under test might be deliberately



Primary current, 10,800 amperes rms a-c component, $T_a = 0.11$ second

Test transformer *A*: 1,000/5, 2.7 square inches iron; secondary circuit resistance —1.36 ohms

Test transformer *B*: 1,000/5, 2.53 square inches iron; secondary circuit resistance—4.04 ohms

Figure 8. Test oscillogram for external fault

unbalanced until failure of the relay occurred.

Figures 8 to 11 are typical oscillograms from a large number of tests. The essential data for each of these oscillograms are given in the captions.

In figure 8, representing an external fault, it is to be noted that there is an initial high peak of differential current which scales 87 amperes maximum instantaneous value. The normal output of transformers *A* and *B* would have been 54 amperes rms a-c component, if they held their ratio. Inspection of the traces representing the output of current transformers *A* and *B* reveals, however, that they do not hold their ratio, and that their output is severely limited by d-c saturation for the first few cycles. On this basis, it is obvious that the high-speed relay sustained a very high percentage unbalance for one peak without tripping, as the relay contact line indicates. A simple high-speed ratio-differential relay with the usual current coils would have tripped under this condition.

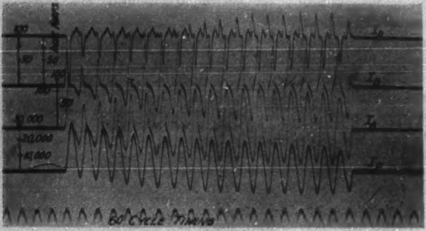


Figure 9. Test oscillogram for external fault

Conditions the same as for figure 8, except that the relay was short-circuited, terminal 1 to 2 to 3 (figure 7)

The peculiar wave shape of the differential current, shown in figure 8, warrants some discussion. The initial high peak is caused by the fact that current transformer *B* became thoroughly saturated by the d-c component a short interval of time before current transformer *A* became saturated. During the interval between the complete saturation of transformer *B* and transformer *A*, when transformer *B* alone was breaking down in ratio, transformer *A* was able to force the peak of differential current through the relay. When saturation was reached in both transformers, however, both of them performed very much as if they were air-core transformers, neither of them having sufficient capacity to hold their ratio with the burdens involved. During the time when both transformers were saturated, both the reduced capacity of the better current transformer as well as the impedance of the differential circuit effectively reduced the magnitude of the differential current. Thus, it will be noted that the difference current is inconsequential for approximately eight cycles after the initial high peak. After approximately eight cycles however, transformer *A*, having a better ratio of iron area to resistance burden, began the process of recovery from d-c saturation so that it was again able to perform somewhat better than transformer *B*. For this reason, a current began to reappear in the differential circuit.

As has been stated, the nominal output of both transformers would have been 54 amperes rms secondary, a-c component, if neither transformer had saturated, this value being derived from the 10,800-ampere symmetrical a-c component of the primary current and the ratio of the current transformers. In order to force this secondary current through the resistance burdens indicated, transformer *B* would have had to develop a flux density of 160,000 lines per square inch, and transformer *A* would have had to develop 51,000 lines of flux per square inch, calculated from the equation:

$$B_m = \frac{IR\,10^8}{4.44nfA}$$

where

B_m = maximum flux density in lines per square inch
n = number of secondary turns
f = frequency in cycles per second
A = cross-sectional area of the iron core in square inches
I = rms secondary amperes
R = total secondary circuit resistance

(This equation has been derived from the familiar transformer equation, $E = 4.44nf\phi_m 10^{-8}$.) The flux density values indicated form a measure of the unbalance between the two current transformers, the flux densities for perfect a-c performance having a ratio of 3.14/1.

The wave form of the differential current in figure 8 was of sufficient interest to arouse speculation concerning what this differential current would look like if the impedance of the relay circuit were zero. In order to obtain data on this point, all three terminals of the relay were short-circuited together and the oscillogram of figure 9 was taken under the same conditions. (No contact line was desired in this case, since the relay element was short-circuited.) Figure 9 shows a similar high initial peak of differential current, which scales 101 amperes. Since there was no differential circuit impedance in this test to form a balancing action between the two transformers, the differential current did not subside to almost zero for several cycles, as in figure 8. The calibration of the oscillograph was the same for both tests.

Figure 10 is an oscillogram for an internal fault with values as given in the caption. The internal fault was simulated by reversing the secondary connections of transformer *B* so that the total current of both transformers passed through the differential circuit of the relay. The time of operation of the relay is scaled from the contact line of the film to be approximately 0.6 cycle. Again, there was considerable saturation of the current transformers, particularly because of the d-c transient, yet prompt

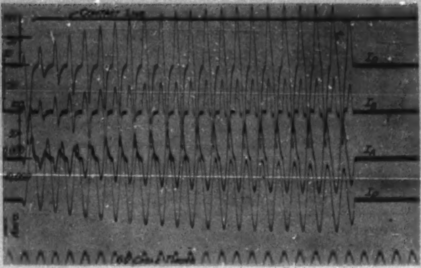

Figure 10. Test oscillogram for internal fault

Primary current, 10,900 amperes rms a-c component, $T_a = 0.123$ second

Test transformers as in figure 8 except secondary circuit resistance for current transformer *B* reduced to 2.44 ohms

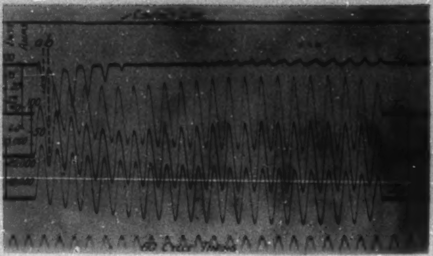

Figure 11. Test oscillogram for external fault

Primary current, 11,000 amperes rms a-c component, $T_a = 0.094$ second

Test transformer *A*: 4 primary, 800 secondary turns, 1,000/5, 4.8 square inches iron, secondary resistance (total) 1.31 ohms

Test transformer *B*: 1 primary, 200 secondary turns, 1,000/5, 1.7 square inches iron; secondary resistance (total) 1.18 ohms

operation of the relay was not affected.

Figure 11 shows another test for an external fault except that a different pair of current transformers was used with a different degree of unbalance, particularly with regard to the cross-sectional area of the iron in the test transformers. In this case, the calculated flux requirements for the a-c symmetrical component alone are as follows:

Transformer *A*—7,100 lines per square inch
Transformer *B*—71,600 lines per square inch

$$\text{Ratio } B/A = \frac{71{,}600}{7{,}100} = 10.2/1$$

In figure 11, the time of the first peak of differential current has been indicated by the dotted line, *a*, and it will be noted that this peak occurs earlier than the peaks of the two restraint, or sum coil, currents as indicated at *b*. This illustrates the meaning of the statement previously made that the differential current tends to be out of phase with the restraint current when the current transformers saturate during through fault conditions.

Summary of Test Results

The tests were made over a wide range of variation between current-transformer designs and loading, as has been indicated in part in figures 8 and 11. The purpose of this was to explore the range of possibilities of the new relay by exceeding the range normally to be expected. For example, it is felt that the conditions of figure 8 are more severe than would normally be expected for a reasonable application of generator differential protection. That is, it appears that the extreme importance of a large generator would justify the application of transformers whose a-c flux requirements for the maximum symmetrical external fault would not exceed the nominal saturation density of approximately 70,000 lines per square inch. Other tests, not described here, were made to cover the conditions imposed when a generator is connected to a double bus through two circuit breakers. In such an application, a heavy current may flow during an external fault from one bus to the other through the two circuit breakers connected to the generator. Such a current, flowing through the two current transformers per phase on the bus side of the generator, would materially increase the duty on them as compared to the duty imposed upon the current transformers in the neutral connection of the machine being protected. The relay performed satisfactorily in these tests.

Since it is obvious that there is a myriad of possibilities between different applications with regard to slight unbalances in iron area and secondary burden in current transformer circuits, the problem is how to best express the permissible variation in general terms. It has been found that the method of analysis used for the test of figures 8 and 11 is the most suitable; that is, where the flux density of the transformer is calculated showing the requirements for the maximum symmetrical current which will be experienced for an external fault. This method gives at once a figure which takes into consideration the factors which tend to unbalance the current-transformer performance for a given application.

A wide variation in permissible loading has been shown by the ratios of calculated flux densities of 3.14/1 for figure 8, and 10.2/1 for figure 11. In general, it was found that a higher ratio was permissible when the maximum calculated flux density for either transformer did not greatly exceed the nominal saturation density of approximately 70,000 lines per square inch.

Conclusions

1. In the past, the application of high-speed (one-cycle) differential protection to generators has required the closest scrutiny of the current-transformer characteristics with respect to the duty imposed. This study involved particular attention to the effect of the d-c component of asymmetrical through faults. In all such cases, careful matching of current-transformer characteristics was required.

2. With the new relay, it suffices to look carefully only at the a-c characteristics of the transformers. The application is thus reduced to the simplicity of the older, slower-speed, induction-type relay, where a consideration of the a-c characteristics of the current transformers was generally sufficient.

3. A means of comparing the duty on the current transformers has been given through the method of calculating the theoretical maximum flux density required for the a-c component. When the resulting figure does not materially exceed the nominal saturation value of 70,000 lines per square inch, an allowable ratio between the values for the two current transformers of 3/1 provides ample safety factor to guarantee satisfactory relay operation.

Frequency Modulation

W. L. EVERITT
FELLOW AIEE

RADIO communication makes use of a medium common to the whole world for the transmission of many signals simultaneously. In order to accomplish this a high-frequency electromagnetic wave has one of its characteristics varied in accordance with the instantaneous variations of the signal to be transmitted. The control of these variations is called modulation. The various simultaneous messages can then be separated by:

(*a*). Differences in the frequency band used.

(*b*). Differences in signal strength.

(*c*). Differences in direction of the source.

The allocation of frequencies and geographic location to stations engaged in different services is now a matter of legislation and international agreement. This regulation is necessary in order to reduce interference to a minimum.

The range of a radio station is limited solely by the point at which undesired interference reduces the quality of the received signal below a certain minimum. The amount of interference which may be tolerated differs with different classes of service, for instance, it would be less on a broadcast program designed to produce pleasure, than on a communication service designed to convey intelligence.

There are five principal sources of interference to radio reception. They are:

(*a*). Interference from other radio stations.

(*b*). Interference from natural electrical disturbances such as thunderstorms (static).

(*c*). Interference from electrical equipment not intended for radio purposes.

(*d*). Interference between identical signals traveling from the station originating the desired signal, but over two different paths. Since radio waves are alternating phenomena resolvable into a band of frequencies, the addition of two similar signals traveling over different paths must take account of both magnitude and phase. Distortion in the resultant signal may result due to the varying phase relations between the components with the same frequency in the two signals. One of the paths is usually caused by reflection from some medium such as the ionosphere. If this path varies in length with time, fading will result. When this produces distortion the phenomenon is called selective fading.

(*e*). Interference from random noise produced in the receiver by fluctuations in the motion of the electrons in the early stages of the amplifiers.

The major problems of the radio engineer are:

I. To obtain the maximum range at the minimum cost.

II. To secure the desired quality in the reproduction of signals.

Because the range is determined by the interference, and the quality is greatly affected by it, the reduction of interference becomes of paramount importance.

The reduction of interference must be accomplished by making use of some characteristic which differentiates the desired signal to a greater or less extent from the undesired interference. Four methods of differentiation have been extensively used. Each method in turn has its limitations. These methods and their limitations are:

1. Use of high power in the transmitter so that the strength of the desired signal will dominate the undesired.

This method is limited by the cost of high powered transmitters and by the interference it introduces to other services. Furthermore it does not affect selective fading since both signals (coming over two paths) are increased by the same amount.

2. Increasing the modulation of the radio wave to the greatest possible value.

This method is limited in amplitude modulation because it is not possible to vary the magnitude of a radio wave by more than 100 per cent and interfering signals, including static, will in general be modulated by similar amounts.

3. Use of selective circuits in the receiver so that only energy in the narrow band of frequencies which includes the desired signal will be received.

This method is limited because a definite band width is necessary for any given quality of reproduction and within this band there may be some portion of the energy in the spectrum of the interference.

4. Use of directive antennas at the receiver so that it is most sensitive to electromagnetic waves coming from the direction of the transmitter creating the desired signal and is insensitive to radiations originating in other directions.

This method is limited by the expense of directional antennas and by the fact that some interference may be originating in the same direction as the desired signal.

It is apparent that the methods just mentioned, taken individually or in combination, do not offer a complete solution of the problem. In fact no complete solution would appear possible, as the ultimate range of any transmission must be determined by the tolerable interference. However, any method which offers increased possibilities in the differentiation between desired signal and interference may be used to improve transmission. *Frequency modulation* offers such an additional method by which interference may be separated from the desired signal and it is the purpose of this paper to outline the principles and practices by which this may be accomplished.

The use and study of frequency modulation is not new. The Poulsen arc, developed before 1914, transmitted continuous-wave telegraph signals in which the frequency was shifted from one value to another when the key was depressed. Carson[1] and Roder[2] made theoretical investigations of the effects of frequency modulation on the spectrum of the modulated wave. Carson's investigation was

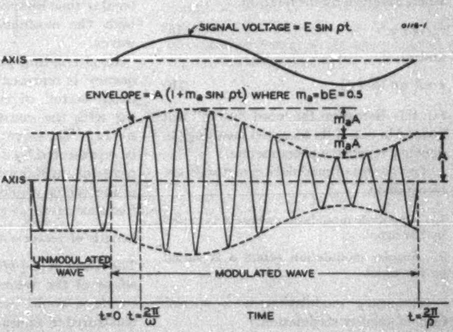

Figure 1. An amplitude - modulated wave

Paper 40-116, recommended by the AIEE committee on communication, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted April 23, 1940; made available for preprinting May 27, 1940.

made to analyze the proposal that frequency modulation could be used to reduce the band width required for a given signal. He proved that, on the contrary, frequency modulation never reduced the band width and might greatly increase it. Mathematics provides a correct answer to questions which are asked by its means, but it cannot be expected to provide answers to questions which are not asked. What was overlooked in the early mathematical analyses was the fact, later demonstrated by Armstrong,[3] and subsequently by Carson[4] and Fry, that frequency modulation provides an important method of distinguishing between desired and undesired signals which occupy the same portion of the frequency spectrum.

It will be necessary to go into some details of the principles of frequency modulation in order to show the reasons for this effect.

Modulation

Modulation of a radio wave is the process by which some characteristic of the radio wave is varied in accordance with the time variation of a signal, such as the instantaneous variations associated with speech, music, or the manipulation of a telegraph key. A general alternating wave may be represented by the equation

$$e=A\sin\theta \qquad (1)$$

where θ is given by the relation

$$\theta=\omega t+\phi \qquad (1a)$$

and so

$$e=A\sin(\omega t+\phi) \qquad (1b)$$

(In this discussion the word "wave" will be used in one of its accepted meanings to denote a repetitive phenomenon.)

Two groups of modulation methods are recognized.

1. **Amplitude modulation where A is varied by the signal.**
2. **Angular modulation where ϕ is varied by the signal.**

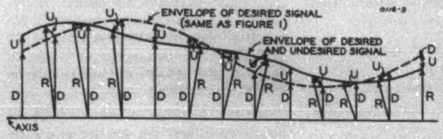
(Frequency modulation is a special form of angular modulation.)

Amplitude Modulation

In an amplitude-modulated wave the amplitude is varied about its mean value in proportion to the signal. Let the original signal (such as the sound pressure on the microphone) be represented by the function $f(t)$. Then the amplitude factor A of equation 1b is modified by $f(t)$ to give the amplitude-modulated wave

$$e=A[1+bf(t)]\sin(\omega t+\phi) \qquad (2)$$

where b is a factor determined by the design and operation of the modulating system and has dimensions such that $[bf(t)]$ is a pure numeric. b is usually a constant, but in some cases it is made a function of audio frequency. For example, if it is made to change with frequency in the proper manner compensation may be secured for defects in the frequency characteristic of some other part of the system.



ENVELOPE OF DESIRED SIGNAL (SAME AS FIGURE 1)
ENVELOPE OF DESIRED AND UNDESIRED SIGNAL
U
R
D
AXIS

Figure 3. Interference with an amplitude-modulated wave of a carrier of slightly different frequency

D—Vector of desired signal
U—Vector of undesired or interfering signal
R—Resultant vector (*D*+*U*) of sum of desired and undesired signals

The amplitude variation cannot carry the amplitude below zero. Therefore the factor b should be so chosen by the operator that $[1+bf(t)]$ never becomes negative. Therefore $[bf(t)]$ should not exceed an absolute value of unity. This absolute value of the maximum of $[bf(t)]$ is called the amplitude *modulation factor* and is given the notation m_a.

If the signal $f(t)$ is sinusoidal with a frequency $p/2\pi$, equation 2 becomes

$$e=A(1+m_a\sin pt)\sin\omega t \qquad (3)$$

The curve of equation 3 is illustrated in figure 1 for $m=0.5$ and $\omega/p=10$. It will be noted that the wave crosses the axis at regular time intervals of $2\pi/\omega$ seconds for both the modulated and unmodulated waves.

In alternating phenomena a single frequency is represented by the projection of a vector of constant length rotating with the constant angular velocity $\omega=2\pi f$. The wave of equation 2 could also be represented by a vector rotating with a constant angular velocity ω, but the length of the vector would be changing at a low frequency rate as given by the equation

$$\text{Length of vector}=A[1+bf(t)] \qquad (4)$$

The term $A[1+bf(t)]$ is called the *envelope* of the wave. In equation 3 the envelope would be $A[1+m_a\sin pt]$ as is illustrated in figure 1.

In drawing vectors which represent alternating phenomena it is common practice to consider that the observer is traveling on a platform which is also rotating about the same center with a velocity ω. The original vector would then appear to be stationary and could be represented by a single drawing. However, if either the magnitude or the phase of the vector is changing with time, a series of successive drawings is necessary to illustrate what is happening.

These successive drawings of stationary vectors for the wave of figure 1 are shown in figure 2 for time intervals of one-eighth the period of the low-frequency wave producing the modulation.

At the receiver the detector produces a response which is proportional to the envelope of the modulated wave (except for the constant component).

Interference of Two Amplitude-Modulated Waves

If a second amplitude-modulated wave of the same carrier frequency and phase is added to the wave of figure 1 the resultant wave will have an envelope which is the sum of the envelopes of the two waves, for the vectors will be adding in phase. The interfering effect will be noticeable if the undesired signal is as much as one per cent of the desired signal. Hence it is desirable to make the value of m_a as large as possible, since the operator of a given communication system cannot control the modulation of the interfering wave with the undesired signal.

If the frequency of the interfering wave is slightly different from the desired wave (the difference being too small to eliminate it by selective circuits) then the interfering wave will produce a variation in the envelope which variation has an amplitude equal to the magnitude of the interfering wave (even if it is unmodulated). This additional variation will occur at a frequency which is equal to the difference between the carrier frequencies of the desired and undesired signals, and will produce a squeal which is further superimposed on the resultant envelope. This is illustrated by the vector diagrams in figure 3, where the undesired signal has a frequency which exceeds the frequency of the desired signal by $1.5\rho/2\pi$. It is seen that the resultant envelope is modified by an additional component equal to the magnitude of the undesired wave, and so introduces interference proportional to the magnitude of the interfering wave.

Again it is apparent that the amplitude of the envelope of the desired signal should be kept as large as possible in order that the interference may be minimized. If equation 2 represents current or voltage, the amplitude of the envelope may be increased by increasing either the power or the amount of modulation (m_a).

Angular Modulation

In angular modulation (of which frequency modulation is a subdivision) the angle ϕ of equation 1*b* is given by a function of time which is related, but not in all cases, directly proportional, to the signal function $f(t)$. The two principal subdivisions of angular modulation which have been extensively studied are phase modulation and frequency modulation.

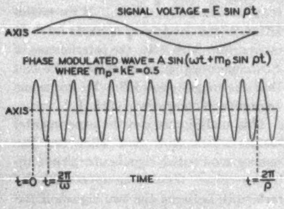


Figure 4. An angular-modulated wave

The 1st, 4th, 7th, 10th, and 13th cycles are shown in detail in figure 5

(*a*). PHASE MODULATION

In this type of modulation the phase angle ϕ is made to vary in accordance with the signal. That is

$$\phi=b_1f(t) \tag{5}$$

where b_1 is a *constant* determined by the design and operation of the modulating system. When equation 5 is inserted in equation 1*b* the wave becomes

$$e=A\sin\left[\omega t+b_1f(t)\right] \tag{6}$$

The maximum value of $b_1f(t)$ is called the *phase modulation factor* m_p. It is the maximum number of radians by which the phase of the carrier is altered during modulation. If the signal is sinusoidal with a frequency $\rho/2\pi$, equation 6 becomes

$$e=A\sin\left[\omega t+m_p\sin\rho t\right] \tag{7}$$

(*b*). FREQUENCY MODULATION

In this type of modulation the *instantaneous frequency* is varied about the average value $\omega/2\pi$ in proportion to the instantaneous value of the signal. By definition, the use of the word "frequency" is extended to the general equations 1 and 1*b* by the relation

$$2\pi f_{\text{inst}}=\frac{d\theta}{dt}=\omega+\frac{d\phi}{dt} \tag{8}$$

Since ω is a constant (2π times the carrier frequency) the signal must modify $d\phi/dt$ so that the instantaneous frequency is given by the relation

$$f_{\text{inst}}=\frac{\omega}{2\pi}+b_2f(t) \tag{9}$$

where b_2 is a design and operating constant. The maximum value of $b_2f(t)$ is the maximum deviation in instantaneous frequency of the modulated wave from the unmodulated one and is called the *frequency modulation factor*, or frequency deviation, m_f. If $f(t)$ is a sine wave with a frequency $\rho/2\pi$ then

$$b_2f(t)=m_f\sin\rho t \tag{10}$$

If equation 10 is combined with equations 8 and 9

$$2\pi f_{\text{inst}}=\omega+2\pi m_f\sin\rho t=\omega+\frac{d\phi}{dt}$$

which gives

$$\phi=\int 2\pi m_f\sin\rho t dt=-\frac{m_f}{f_\rho}\cos\rho t$$

where f is the frequency of the modulating signal. If this phase angle is inserted in equation 1*b* the result will be

$$e=A\sin\left[\omega t-\frac{m_f}{f_\rho}\cos\rho t\right] \tag{11}$$

Equations 11 and 7, which apply to a signal with a single frequency, do not differ appreciably (except for a 90-degree shift in the modulation phase). In equation 11 the maximum shift in phase (corresponding to the phase modulation factor m_p) will be

$$m_p=\frac{m_f}{f_\rho} \tag{12}$$

where m_f is the frequency deviation and f_ρ the modulating audio frequency. The value of m_f when f_ρ is the maximum audio or signal frequency to be transmitted is called the *deviation ratio*.

m_p in phase modulation and m_f in frequency modulation are arbitrary design factors. Unlike amplitude modulation they are not restricted to a maximum value of unity, for m_p may be hundreds of radians or m_f thousands of cycles per second if desired. The limitations on m_p and m_f will be determined by the allowable frequency spectrum and will be discussed later.

The distinction between phase and frequency modulation is as follows: if the frequency, but not the intensity of the modulating signal changes

m_p is constant in phase modulation.

m_f is constant in frequency modulation.

It follows from equation 12 that in frequency modulation the phase deviation m_p is inversely proportional to the modulating frequency. On the other hand in phase modulation the frequency deviation is directly proportional to the modulating frequency.

Figure 4 is an illustration of the angular modulation as represented by equation 7 for the case where $m_p=0.5$ and $\omega/\rho=12$. On a casual examination this would appear to be a single frequency wave. However, the intervals at which it crosses the axis vary throughout the audio cycle. In order to show this the 1st, 4th, 7th, 10th, and 13th cycles are expanded and shown in figure 5. It is seen that the varying shift in phase also produces a change in frequency which varies throughout the low-frequency cycle.

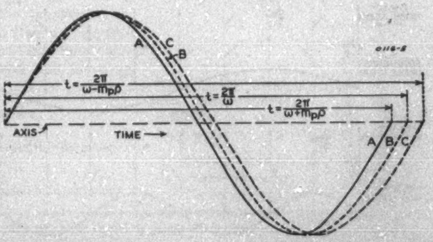

Figure 5. Expansion of individual cycles in figure 4

A—1st and 13th cycles of figure 4

B—4th and 10th cycles of figure 4

C—7th cycle of figure 4

The successive vector diagrams for the angular-modulated wave of figure 4 (corresponding to the diagrams of figure 2 for an amplitude-modulated wave) are shown in figure 6. The signal wave is included for identification of the various instants.

The difference between phase and frequency modulation may be illustrated by the way the motion of the resultant vector would appear to an observer riding with the carrier vector. In phase modulation, two audio signals of equal amplitude, but of different frequencies, would produce equal angular *amplitudes* in the apparent swing of the resultant vector. In frequency modulation two audio signals of equal amplitude would produce equal maximum angular *velocities* in the apparent swing of the resultant vector. In this latter case (frequency modulation) the maximum angle of swing would be inversely proportional to the audio frequency (as is indicated by equation 12). This is illustrated by figure 7 where the vectors for both frequency and phase modulation are drawn for two signals with an audio-frequency ratio of two to one. Note that in phase modulation the maximum angle ϕ_m is the same for both signals while for frequency modulation the maximum angle ϕ_m for signal A (the lower frequency) is twice that for signal B. Since the angular *velocity* is proportional to the instantaneous value of the signal in frequency modulation the vector reaches its maximum angle of deviation when the signal is zero while in phase modulation it reaches its maximum angle of deviation when the signal is a maximum.

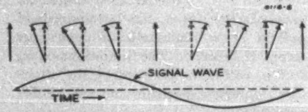

Figure 6. Vector diagrams of the angular-modulated wave of figure 4 for successive instants

Solid-line vectors are vectors of modulated wave

Dashed-line vectors are vectors of unmodulated wave

Other Types of Angular Modulation

Phase and frequency modulation are not the only possible types of angular modulation, but are only two members of an infinite group. Other possible types are:

(*c*). Angular Acceleration Modulation

In this type of modulation the second time derivative of ϕ is directly proportional to the signal function

$$\frac{d^2\phi}{dt^2}=b_3f(t)$$

In this type m_p would be inversely proportional to the square of the audio frequency.

(*d*). nth Order Modulation

In this general type of angular modulation the nth derivative of ϕ is directly proportional to the signal function.

$$\frac{d^n\phi}{dt^n}=b_{n+1}f(t) \tag{13}$$

In this type m_p would be inversely proportional to the nth power of the frequency for modulating signals of equal intensity.

In radio transmission by angular modulation means are provided at the receiver so that the detected signal is proportional to the angular modulation (of the particular subdivision selected) and at the same time this detected signal is made unresponsive to amplitude variations. These means will be discussed in more detail later.

Note: ϕ_m is same for both signals for phase modulation. ϕ_m is inversely proportional to signal frequency for frequency modulation. Maximum velocities of vectors are same for both signals for frequency modulation

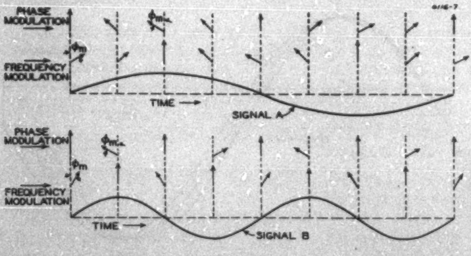

Figure 7. Comparison of phase and frequency modulation by means of vector diagrams

Interference of Two Angular-Modulated Waves

When two angular-modulated waves of the same carrier frequency are added together, the total angular modulation is not the sum of the two individual modulations. This is in distinct contrast to amplitude modulation where the resultant envelope is the sum of the individual envelopes.

This can be illustrated by figure 8 where an angular-modulated wave B is represented by a vector whose angle is changing with time. This is added to a larger vector A which for the moment will be assumed to be unmodulated. The resultant vector R will be the sum of the two vectors.

It is apparent that if B is less than A, then no matter what the total angular variation of B may be (even if it is hundreds of radians) the total angular variation between R and A cannot exceed $\tan^{-1}(B/A)$. For instance if $B/A=0.5$ the maximum value of m_p for the vector R when A is unmodulated is $m_p=0.46$. If $B/A=0.5$ and A in turn has its angle modulated, then the difference between the angle of A and that of R cannot exceed 0.46 radian at any instant. If the modulation factor (m_p) of A is made large in comparison with 0.46, the interference of B becomes negligible, in spite of the fact that the magnitude of B is by no means negligible in comparison with A.

This analysis justifies the experimental results which show that when two frequency-modulated signals are picked up by a receiver, there is no appreciable interference between the two signals if the stronger exceeds the weaker by a ratio of two to one or more.

It will be seen that the greater the value of m_p used for the desired signal the greater is the discrimination against the undesired signal, but this discrimination is not affected by the value of m_p used in the undesired signal.

The discrimination against interference obtained by angular modulation applies to all five types of interference enumerated in the early part of the paper. In particular static may be represented as a vector of varying phase and magnitude. The selective circuits of the receiver admit only those components within the band to which it is receptive. If the amplitude of the admitted noise does not exceed half the amplitude of the desired wave, a very small amount of noise will be introduced into the output. The greater

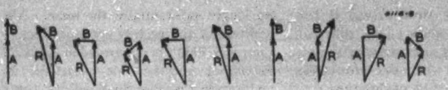

Figure 8. Vector diagrams showing interference in angular modulation

A is vector of desired signal—unmodulated
B is vector of interfering signal (same carrier)
R is vector of total wave $(A+B)$

the average phase deviation in comparison with the angle 0.46 (approximately 0.5) the greater will be the discrimination against the noise. It should also be observed that components of the noise vector which differ in frequency from the carrier by superaudible frequencies, will produce superimposed angular velocities above audibility and so do not contribute to the noise, as long as the noise is small compared with the signal.

In radio operation it will be found that if a portable receiver is driven in an automobile away from a frequency-modulated transmitting station, no appreciable noise will be experienced until the desired field strength drops to twice the noise field strength (taking into account only those components of noise accepted by the selective circuits of the receiver). The noise then rises rapidly, so that a sharp threshold is experienced.

Within the distance limited by the threshold, the signal-to-noise ratio can be improved by either increasing the power or increasing the modulation factor (either phase or frequency). Since power is proportional to the square of voltage or current in a given system, doubling the frequency deviation in frequency modulation has the same effect on the signal-to-noise ratio as increasing the transmitted power four times. In general an increase in the maximum frequency deviation by a ratio n would be equivalent in its effect on the signal-to-noise ratio to an increase in power by the ratio n^2.

The actual voltage produced by noise in the amplifier of a radio receiver increases with the width of the band accepted, the rate of increase depending on the type of noise. This introduces some disadvantage to the use of a wide band, because a stronger desired wave is necessary to insure that the desired voltage shall exceed the noise voltage.

R. F. Guy of the National Broadcasting Company reported before the Federal Communications Commission that in experiments with a one-kw transmitter and an antenna 1,000 feet high, the threshold for a value of m_f equal to 75 kilocycles was at 86 miles, while with an m_f of 15 kilocycles the threshold was at 100 miles due to the smaller noise voltage accepted by a more selective receiver. Within the threshold distances, however, there is a greater discrimination against noise with the greater frequency deviation.

The second major objection to the use of a large frequency deviation is that it would limit the number of stations which can serve a given area if a fixed total band width is allowed for the service.

A compromise must be reached and standard set before the use of frequency modulation is generally adopted so that the receivers may work with the transmitters. In order to study the possible or required allotment, a spectrum analysis must be made of the different classes of modulation.

Spectrum Analysis of Amplitude Modulation

The wave of equation 2 may be expanded by the use of simple trigonometric identities. This equation becomes

$$e=A\sin\omega t+\frac{mA}{2}\cos(\omega-p)t-\frac{mA}{2}\cos(\omega+p)t \qquad (14)$$

Equation 14 shows that the wave which is amplitude modulated by a single frequency may be analyzed into three component frequencies with the following designations:

$A\sin\omega t$	The carrier
$\frac{mA}{2}\cos(\omega-p)t$	The lower side frequency
$\frac{mA}{2}\cos(\omega+p)t$	The upper side frequency

The three components may be represented by three vectors rotating at different angular velocities. Again if the observer were rotating with the carrier vector, this vector would appear to be stationary. The upper side-frequency vector would appear to be rotating *counterclockwise* at a velocity p and the lower side frequency would appear to be rotating *clockwise* at the same velocity p.

The three vectors corresponding to the wave of figure 1 are shown in figure 9. It will be observed that the upper and lower side-band vectors add together to form a vector M called the modulation vector, which is always in phase with the carrier vector, but which varies in magnitude.

The three component frequencies of equation 6 are represented graphically in figure 10. This is shown primarily so that it may be compared later with the frequency spectrum used in frequency modulation.

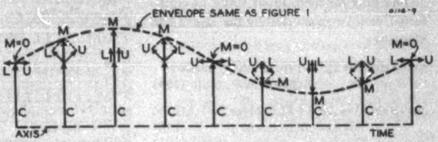

Figure 9. Vector diagram of carrier and side frequencies in an amplitude-modulated wave

C—Carrier vector (constant length)
U—Upper-side-frequency vector
L—Lower-side-frequency vector
M—Modulation vector (sum of *U* and *L*)
Vector of complete wave is sum of *C* and *M*

If the original signal were a complicated sound wave instead of a single frequency, a spectrum analysis would show it to be represented by a band of frequencies. The lower and upper side frequencies would expand into two bands of frequencies each as wide as the band of the original audio signal. For instance if the signal were restricted to a band of 0–5,000 cycles the two side bands would extend from 5,000 cycles below to 5,000 cycles above the carrier frequency. Since the quality of a signal depends upon the width of the band which may be transmitted, an improvement in the quality of transmission would require an extension of the frequency spectrum occupied by the radio

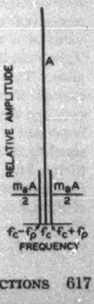

Figure 10. Spectrum analysis of an amplitude-modulated wave

f_p—Audio frequency
A—Carrier amplitude
m_a—Modulation factor=0.5 in this case

wave. However, the narrower the frequency band which is used the greater will be the number of stations which can be accommodated. In practice a compromise must be made. Standard broadcasting stations in North America are assigned carrier frequencies in the range of 550 to 1,600 kilocycles, these assignments being separated at intervals of 10 kilocycles. In order to prevent interference, selective circuits are required in the receiver which are so sharp in most commercial models that side-band components more than 3,000 cycles away from the carrier are greatly attenuated. Hence the quality which is permissible in practical operation is limited by the major problem of interference.

Spectrum Analysis of Angular Modulation

The angular-modulated wave of equation 7 may be expanded by the use of the identities

$$\sin(p \sin x) = 2[J_1(p) \sin x + J_3(p) \sin 3x + J_5(p) \sin 5x + \ldots.] \quad (15a)$$

$$\cos(p \sin x) = J_0(p) + 2[J_2(p) \cos 2x + J_4(p) \times \cos 4x + J_6(p) \cos 6x + \ldots] \quad (15b)$$

where $J_n(p)$ is the nth order Bessel function of the first kind. Equation 7 may be written

$$e = A[\sin \omega t \cos(m_p \sin \rho t) + \cos \omega t \times \sin(m_p \sin \rho t)] \quad (16)$$

If equations 15*a* and 15*b* are inserted in equation 16 the following result will be obtained

$$\begin{aligned} e = A\{&J_0(m_p) \sin \omega t + \\ &J_1(m_p)[\sin(\omega+\rho)t - \sin(\omega-\rho)t] + \\ &J_2(m_p)[\sin(\omega+2\rho)t + \sin(\omega-2\rho)t] + \\ &J_3(m_p)[\sin(\omega+3\rho)t - \sin(\omega-3\rho)t] + \\ &J_4(m_p)[\sin(\omega+4\rho)t + \sin(\omega-4\rho)t] + \\ &\ldots\ldots\ldots\ldots\ldots\ldots + \\ &J_n(m_p)[\sin(\omega+n\rho)t + \\ &(-1)^n \sin(\omega-n\rho)t]\} + \\ &\ldots\ldots\ldots\ldots\ldots\ldots \end{aligned} \quad (17)$$

This indicates that there are an infinite number of side frequencies for a single-frequency signal. However this is not as bad as might at first appear because for any given value of m_p, there will be a value of n above which the coefficients $J_n(m_p)$ fall off rapidly and become negligible. This is shown in figure 11. For example if m_p is one-half radian or less, only the first pair of side frequencies is important. On the other hand if m_p is equal to 20 radians, side frequencies out to the 24th pair would be appreciable. For large values of n this rapid falling off of $J_n(m_p)$ occurs just beyond $n = m_p$. Observe also that the value of the carrier component is always reduced when modulation occurs since $J_0(m_p)$ is less than one for all values of m_p different from zero. This is in contrast with amplitude modulation where the value of the carrier is not affected by modulation.

Figure 4 was drawn for a phase-modulation factor of 0.5 and so the first pair of side bands are the only ones of importance. If all other side bands are neglected the vector diagrams including the side bands for different instants of figure 4 can be shown as in figure 12. The signal wave is shown for identification. The carrier and resultant vectors are the same as those shown in figure 6. The modulation vector, which is the sum of the two side-band vectors, is always 90 degrees out of phase with the carrier and varies in magnitude in the same way that the modulation vector varies in amplitude modulation. The neglect of higher-order side frequencies is the same as an assumption that there is a negligible difference between the arc and a tangent line of the same length when the angle is small.

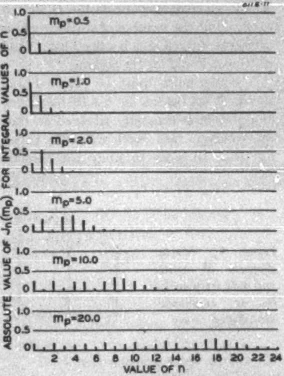

Figure 11. Values of the Bessel function of the first kind for integral orders

When the modulation vector is added to the carrier vector it causes the resultant vector alternately to advance beyond and retard behind the carrier vector. The maximum advance and retardation is approximately one-half radian. The length of the resultant vector is substantially constant. If the additional side bands were included the length of R would be exactly constant.

If the phase modulation exceeds one-half a radian additional side bands must be included because the arc and chord are no longer substantially the same. The addition of the vectors corresponding to these side bands is illustrated in figure 13 for $m_p = 1$ and for one-quarter of an audio cycle, the other three-quarters being similar. It will be noticed that each pair of side bands has associated with it a modulation vector which maintains a constant phase with respect to carrier (assuming that phase reversals are taken care of by negative signs).

If the modulated wave represents a quantity whose square is proportional to power in a given system the *average* power in an angular-modulated wave is not changed by the modulation, as the rms value of the wave is not modified if the amplitude remains constant. Therefore the square root of the sum of the squares of the carrier and all the side-band components remains constant for all values of m_p. The side-band power is obtained by a reduction in carrier power. This is also proved by the well-known relation

$$J_0^2(m_p) + 2\sum_{n=1}^{n=\infty} J_n^2(m_p) = 1$$

for all values of m_p. The number of terms which are of importance in the infinite series can be evaluated by setting

$$J_0^2(x) + 2\sum_{n=1}^{n=s} J_n^2(m_p) \geq \lambda$$

Then if λ is taken as some value less than unity, the sum can terminate with a finite value of n equal to s. If λ is equal to 0.999 then 99.9 per cent of the energy in the wave would be due to side-band components corresponding to values of n equal to or less than s.

For example, if $m_p = 4$ and six components are taken in each side band

$$\begin{aligned} J_0^2(m_p) + 2\sum_{n=1}^{n=6} J_n^2(m_p) &= 0.157688 + \\ &2(0.004356 + 0.132569 + 0.185072 + \\ &0.079017 + 0.017450 + 0.002411) \\ &= 0.999438 \end{aligned}$$

and all the components corresponding to $n > 6$ would contain only 0.0562 per cent of the energy.

The constancy of power output is in marked contrast to amplitude modulation where the carrier power remains constant and the side-band power is added. For that reason certain problems in design are simplified in a phase- or frequency-modulated transmitter. This will be discussed in the section on transmitters.

Comparison of the Spectra of Phase and Frequency Modulation

In phase modulation the value of m_p is made directly proportional to the maxi-

Table I

Audio Frequency	m_p for 60,000-Cycle Deviation	Approximate Number of Side-Band Components Required	Approximate Band Width in Kilocycles
30	2,000	4,030	120.06
60	1,000	2,020	120.20
600	100	208	124.8
2,500	24	46	140
3,000	20	24	144
5,000	12	30	150
10,000	6	16	160
15,000	4	12	180

mum value of the signal. If two different audio frequencies have equal amplitudes, and modulate the signal in succession, the same number of side-band components would be necessary for each case and these components would have the same relative magnitude. It has been shown that the advantage of angular modulation in the reduction of interference requires the use of large values of m_p for the desired signal. If the value of m_p for a special case is taken equal to 20, then by figure 11 it is apparent that approximately 24 side-band components would be desirable for the upper side band and a similar number for the lower side band. Therefore if an audio signal of high quality containing components up to 15,000 cycles were to be transmitted, a band width of approximately 2×24×15,000 or 720,000 cycles would be required. This is obviously impracticable. For this reason phase modulation (as distinguished from frequency modulation) has not been used for radio transmission.

In frequency modulation the value of m_f is made directly proportional to the maximum value of the signal. If two different audio frequencies have equal amplitudes and modulate the signal in succession with equal values of m_f, by equation 12 the values of m_p for the two cases will be inversely proportional to the audio frequency. Thus if m_p is equal to 4 for 15,000 cycles it would be equal to 40 for 1,500 cycles and equal to 400 for 150 cycles. A study of figure 11 shows that the number of components of appreciable magnitude in each side band is slightly in excess of m_p. Therefore as the modulating frequency is reduced, the number of components necessary increases, and the modulated wave occupies almost a constant band width in the spectrum. As an example consider a case where the maximum frequency deviation is assumed to be 60,000 cycles. Then if a high quality signal is to be transmitted, frequency components in this signal up to 15,000 cycles might be desired. If the wave were frequency modulated with a 60,000 cycle deviation ($m_f=60{,}000$) at 15,000 cycles m_p would equal 60,000/15,000=4 radians. For this case figure 11 shows that approximately six components in each side band separated at intervals of 15,000 cycles are desirable and the corresponding band width would be 2×6×15,000 or 180,000 cycles. On the other hand if the wave were to be frequency modulated with a 60,000 cycle deviation by a 3,000 cycle wave $m_p=60{,}000/3{,}000=20$ and approximately 24 components in each side band separated at intervals of 3,000 cycles would be desirable. The band width for this signal would be 2×24×3,000=144,000 cycles which is somewhat less than that needed for $m_p=4$ at 15,000 cycles. Table I is constructed for a maximum deviation of 60,000 cycles.

The spectrum analysis for a deviation of 60 kilocycles and modulating frequencies of 2,500, 5,000, 10,000, and 15,000 cycles is shown in figure 14 and it is apparent that the signal is contained within a band width of approximately 200 kilocycles in all cases. In practice, no audio signal would contain only the higher audio frequencies and so it is found practicable to use a deviation of m_f of 75,000 cycles for a band width of 200 kilocycles.

The spectrum analyses for a modulating frequency of 15,000 cycles and deviation frequencies of 30, 15, 7.5, and 3.0 kilocycles are shown in figure 15.

It is apparent from figures 14 and 15 that when the deviation frequency is large compared with the audio frequency, the band width required is approximately twice the deviation frequency while when the audio frequency is large compared with the deviation frequency the band width is twice the audio frequency. The latter case coincides with the situation in amplitude modulation. In other words the band width required is approximately twice the larger of the two frequencies (audio or deviation). If the audio and deviation frequencies are approximately equal the band width required is approximately four times that of the larger frequency. (See figure 15 for $m_p=0.5$, 1, and 2.)

The spectra of figures 14 and 15 may be used for any other combinations of audio and deviation frequencies which have the same deviation ratio m_p by modifying the scale of abscissa so that the interval between adjacent components is equal to the audio frequency.

The reader must be cautioned that if a signal contains two or more audio frequencies, the resultant spectra cannot be obtained by adding the spectra resulting from each audio frequency alone (as can be done in amplitude modulation). However, the total spectra will remain approximately within the limits set by the maximum frequency deviation when the latter is large.

Although the discrimination against noise is proportional to m_p, it is impracticable to use large values of m_p at all audio frequencies because of the band width involved. However, noise and interference is the composite result of a larger number of noise components. If frequency modulation is employed, the maximum value of m_p is obtained for each audio component in the signal which will at the same time keep the side-band components within the limits in the spectrum assigned to the transmission. Therefore frequency modulation is the type of angular modulation which reduces the composite noise effect to the greatest practicable extent.

If the maximum modulation factor m_p (deviation ratio) is low, m_p less than 0.5, frequency modulation does not appear to have any advantages over amplitude modulation. The early proposals for the use of frequency modulation envisioned this method of operation and so were dis-

Practical Considerations in Frequency Modulation

It has been shown that the reduction of interference makes frequency-modulated transmitters most desirable for the transmission of high-quality signals. However these transmitters require relatively large frequency bands. Therefore frequency modulation, or F-M, does not appear to be feasible in the present broadcast band. For high-quality broadcasting they should be allocated to high frequencies where band widths of 200 kilocycles are available. The Federal Communications Commission has assigned the frequencies from 42 to 50 megacycles for this service or a total of 40 channels. This is in the range of the so-called ultrahigh frequencies.

Radio waves with frequencies of the order of 40 megacycles and above are not reflected from the ionosphere, and so their range is limited by the curvature of the earth. For the same reason static is greatly reduced at these frequencies because the energy which lies in the ultrahigh-frequency spectrum and which is originated by electrical disturbances at distant points on the earth's surface cannot travel to the receiver over long distances. Other factors also reduce static at high frequencies. As an average, the static voltage producing interference in a receiver with a given band width and tuned to 40 megacycles is about $^1/_{40}$ of the static voltage which would be picked up by a receiver of the same band width tuned to 1,000 kilocycles. It is also possible to transmit a wide-band audio signal which requires corresponding wide side bands at ultrahigh frequencies because for practical reasons it is not desirable to assign carrier frequencies as close together as in the standard broadcast band and so sufficient band width is available for high-quality transmission. Therefore ultrahigh frequencies inherently offer an improvement in quality whether amplitude or frequency modulation is used.

However, there are three important difficulties with ultrahigh-frequency transmission for broadcasting purposes. The first difficulty is the effect of the curvature of the earth on ultrahigh frequencies. Because there is no reflection from the ionosphere, it is frequently stated that the limit of transmission for these frequencies is the distance from the transmitting antenna to the horizon. The equation for this distance is

$$d = 1.22\sqrt{H} \qquad (18)$$

where

d is the distance to the horizon in miles
H is the height of the transmitting antenna in feet

For a height of 400 feet the distance to the horizon would be only 24.4 miles.

Within this distance the field strength of the signal is given approximately by the equation[6]

$$E = \frac{0.0105\sqrt{WGHAF}}{D^2} \qquad (19)$$

where

E = field strength in microvolts per meter
W = power in watts
G = gain of the antenna over a half-wave dipole
A = receiver antenna height in feet
F = frequency in megacycles
D = distance in miles

The formula and the statement that the transmission is limited to the horizon are not strictly true because it is found that diffraction and refraction of the waves produce a signal[7] beyond the horizon, but this signal falls off more rapidly than the inverse-distance-squared term of equation 19.

The second difficulty with ultrahigh-frequency transmission is the noise produced locally by electrical apparatus. The principal sources of this noise are automobile ignition and fever therapy machines. These sources might be eliminated in time by legislation requiring adequate shielding.

A third difficulty with ultrahigh-frequency transmission is the sharp shadows thrown by buildings, hills, etc. Sharp shadows are produced in the field of any wave motion when the interfering bodies have dimensions large in comparison with the wave length, and so are particularly apparent at ultrahigh frequencies (short wave lengths).

Because of these difficulties the transmission of amplitude-modulated waves at ultrahigh frequencies has not made very much progress for broadcast transmission. However, these difficulties are only aspects of the fundamental problem pointed out at the beginning of the paper, that radio transmission is limited by the ratio of interference to signal. It has been shown that frequency modulation offers an important improvement in the solution of this problem. By its means the signal-to-noise ratio at any fixed distance may be increased. It seems probable an increase in transmission range may be secured by frequency modulation due to the greater signal-to-noise ratio and this may make economically feasible the use of ultrahigh frequencies for broadcasting purposes.

In field tests, adequate signals for the operation of an F-M receiver at two to three times the horizon distance are regularly reported when the transmitter is a high-powered one.

The wide band width which is required for frequency modulation is compensated

for by the reduction in interference between two stations on the same channel. In amplitude modulation, interference is caused if an undesired signal is one per cent of the desired signal. It has been shown that in F-M a ratio of two to one between desired and undesired signals is sufficient. If two stations of equal power and located in neighboring cities should operate on the same channel, there would be only a small territory about half way between the two stations where there would be any interference. Even in this territory, relatively simple directional antennas would be sufficient to pick out one station or the other. Therefore numerous stations could be located throughout the nation on the same carrier frequencies.

I. R. Weir, of the General Electric Company reported before the Federal Communications Commission that in their experiments they used a 150-watt transmitter at Albany and a 50-watt transmitter at Schenectady, a distance of 14.5 miles. They operated both transmitters on the same frequency with both frequency and amplitude modulation. In driving a car equipped with a receiver along a line between the two stations the following results were obtained:

Type of Modulation	Interference-Free Range of Albany Station	Transitional Distance With Interference	Interference-Free Range of Schenectady Station
Frequency	10.5	1.0	3.0
Amplitude	3.3	11.7	0.5

A further advantage of frequency modulation in the operation of the transmitter and receiver is that nonlinear distortion in frequency modulation is not affected by the nonlinearity of the tubes, as their nonlinearity is a function of amplitude. In F-M nonlinear distortion depends only on circuit design, that is, on nonlinear relations which are a function of frequency. For that reason it is claimed that high-quality reproduction is more practicable.

Frequency-Modulation Receivers

In the discussion of F-M receivers and transmitters, a certain familiarity with communication theory must be assumed in order to conserve space. The discussion will deal with present commercial practice.

Frequency-modulated receivers differ from amplitude-modulation receivers in three important respects. They are:

(*a*). The inclusion of a *limiter* to remove any amplitude modulation resulting from an interfering signal.

(*b*). The use of a special detector circuit called the discriminator to change the frequency modulation into a variable-amplitude signal.

(*c*). The use of a wide-band intermediate amplifier.

In addition it is much more important in a frequency-modulation receiver to have a high-gain intermediate-frequency amplifier, because the operation of the limiter is dependent upon a certain minimum signal being applied to its input. Also, if advantage is to be taken of the high-quality transmission which is possible with F-M, a better-than-average audio system and loud speaker should be included.

Except for these differences, the F-M receiver will follow the practice of amplitude-modulated receivers. The use of superheterodyne receivers is universal.

If a tuned-radio-frequency amplifier has impressed upon its grid a high-frequency voltage exceeding a certain minimum amplitude, the radio-frequency current in the tuned plate circuit will be practically independent of the magnitude of the input. This is because after the radio-frequency component of voltage in the plate circuit has reached an amplitude equal to the d-c component of the plate voltage no further increase in the radio-frequency component can be obtained for the instantaneous value of plate voltage cannot be driven negative. By the use of a high-gain tube and low values of plate voltage, saturation at relatively low values of grid excitation may be obtained. Figure 16 shows the circuit and the limiting action for a typical commercial F-M receiver. The operation of the limiter is the same as that of a class *C* amplifier[8] and the use of a bias obtained by a resistance in the grid circuit assists in securing a flat curve.

The use of a limiter is necessary because any amplitude modulation which reaches the detector will also produce amplitude variations in the reproduced signal. *The use of the limiter or its equivalent at the receiver is the most important component in an F-M system, for no reduction in interference will occur without its operation.* The limiter is possible in frequency modulation because the saturation does not affect the instantaneous frequency of the output.

The elimination of hum due to the use

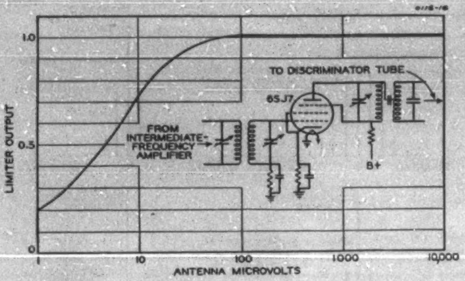

Figure 16. Characteristic and circuit of a limiter

of a-c supplies in receivers has also been a problem for many years. The principal source of this hum is amplitude modulation produced in the receiver by the hum component of the rectified d-c plate supply and by the heating of the cathodes by alternating current. If this occurs in the early stages of the receiver it is amplified along with the signal. While this hum level is reasonably well controlled in modern receivers, the limiter in a frequency-modulated receiver provides an additional improvement. This is particularly important because the elimination of other sources of interference makes the reduction of hum to an extremely low level much more desirable.

Because the audio amplifier and loudspeaker must reproduce the amplitude variations of the original signal, the discriminator or detector circuit must change the frequency variations into amplitude variations. The most common discriminator circuit in use is that of figure 17. The tuned transformer L_1-L_2 has a split secondary feeding two diode plates with the resistance loads R_1 and R_2. The voltage E_3 will be 90 degrees out of phase with the voltage across L_2 at the resonant frequency of L_2-C_2. The radio frequency across diode 1 in series with resistance R_1 is represented by the vector $E_a=E_1+E_3$ while that across diode 2 in series with resistance R_2 is $E_b=E_2+E_3$. When the output of the discriminator is at the intermediate frequency the phase relations will be those shown in diagram *A*. However, when the frequency shifts, the voltage across L_2, (E_1-E_2), shifts in phase. It can be shown that this voltage will follow the locus indicated by the circles. Hence E_a and E_b change in magnitude, one decreasing and the other increasing. By detector theory[5] the instantaneous value of the voltage across R_1 is proportional to E_a while that across R_2 is proportional to E_b. Therefore the instantaneous voltage E_4 supplied to the audio amplifier changes. Increases in frequency make E_4 positive and decreases make it negative.

The relation between the frequency deviation and the instantaneous value of E_4 is also shown in figure 17 for a typical receiver. The circuit constants must be selected so that the straight-line portion of the characteristic will accommodate the frequency shift which is used at the transmitter. The linearity of this characteristic affects the nonlinear distortion in the reproduced signal. It should be observed that its linearity is not a function of the tube characteristic. This makes it apparent that it is necessary to adopt standards at both receiver and transmitter which will be co-ordinated.

After a hearing before the Federal Communications Commission where all the problems were thoroughly discussed, the band width of 200 kilocycles per channel was adopted as standard. The allocation of channels adjacent to each other in the range of 42 to 50 megacycles simplifies the problem of receiver design, since no band-switching equipment will be required.

Because the intermediate amplifier must amplify a wider band of frequencies than is necessary in amplitude modulation a higher intermediate frequency is used. The present standard adopted is 4.3 megacycles for the intermediate carrier frequency.

A system which uses negative-frequency feedback in the receiver[8] has been proposed. It accomplishes similar results to those obtained by the use of the limiter, but as it is not at present available commercially, it will not be discussed here, although additional advantages are claimed for it.

Receivers are being manufactured which receive both amplitude and frequency modulation. In these combined receivers separate intermediate frequency transformers and detectors must be used. This makes the combination receiver somewhat more complicated, but complicated circuits have never been a bar to commercial production. This is exemplified by superheterodyne receivers retailing for $10 which have more extensive circuits than $200 sets of 15 years ago.

Frequency-Modulation Transmitters

Two important and quite different methods of obtaining frequency modulation are in use at the present time. A third method has also been announced.

The method proposed by Armstrong[9] makes use of the fact that for low values of m_p (m_p less than 0.5) the fundamental difference between amplitude and phase modulation lies in the phase relation between the carrier and side-band vectors. This is illustrated by a comparison of figures 9 and 12. Balanced modulators have been extensively used[5] in carrier-current systems to obtain the two side bands of amplitude modulation and eliminate the carrier. In the Armstrong system the carrier output of the oscillator is shifted 90 degrees and then used in a balanced modulator to obtain side-band components corresponding to amplitude modulation with this carrier phase. The output is then added back to a carrier component with the phase of the oscillator to form a phase modulation system. The maximum allowable modulation factor m_p produced with these components is 0.5 since only one pair of side frequencies is available.

A block diagram showing the Armstrong system is shown in figure 18. The

several components required will be discussed in turn.

This method is fundamentally a phase-modulation system, but it may be converted into a frequency-modulation system if an audio equalizer is used before the modulation. The required characteristic of this equalizer is that the output voltage must be inversely proportional to the audio frequency of the input voltage. With this equalizer in the audio system the phase modulation will be inversely proportional to the audio frequency of the original signal. It has been shown that this is the requirement for frequency modulation and so the combination produces true frequency modulation.

It has been explained that with this system m_p is limited to a maximum value of 0.5, in the original modulation. On account of the characteristic of F-M which has been discussed, this maximum value of m_p can only be secured at the lowest audio frequency to be transmitted. The value of m_p at higher frequencies will be inversely proportional to the audio frequency. Then if a range from 40 to 15,000 cycles is to be transmitted the maximum value of m_p at 15,000 cycles will be $40/15{,}000 \times 0.5 = 0.0013$.

Such a method of obtaining frequency modulation, if used alone, would be entirely impractical since operation would be restricted to such low values of m_p and the advantages of frequency modulation lie in the use of large values.

If a radio-frequency amplifier has a large grid bias and relatively large radio-frequency voltage applied to its grid, the plate current will flow in pulses[5] containing harmonics of the grid exciting voltage. If the plate circuit is tuned to a harmonic of the grid voltage, the voltage across the tuned circuit will have a high value at this harmonic. For efficient operation this harmonic should be a low one, say the second or third. When tuned to a second harmonic the combination is called a frequency doubler.

It has been found that a frequency doubler also doubles the phase or frequency shift if an angular modulated wave is applied to the grid, and therefore doubles the value of m_p and also m_f for such a wave. A series of n doublers would multiply m_p by 2^n.

If the method of obtaining frequency modulation now being discussed is operated with a relatively low carrier frequency and the output is passed through a sequence of doublers or triplers, the value of m_p can be correspondingly increased. It has been shown that if a deviation of 75,000 cycles is desired, the value of m_p at an audio frequency of 15,000 cycles would be $75{,}000/15{,}000 = 5$. It has also been shown that for the wide audio range of 40–15,000 cycles the n_p which can be initially produced by the Armstrong method at an audio frequency of 15,000 cycles is 0.0013. Therefore the amount of multiplication of m_p required is approximately $5/.0013 = 3{,}750$. The number of doublers required is then obtained by the solution of the equation

$$2^n = 3{,}750$$

or

$$n = 12 \text{ nearly}$$

If a final carrier frequency of 41 megacycles is to be used and straight multiplication were to be employed, the carrier frequency at which the initial modulation should take place would be determined by the frequency multiplication required. In this case

$$\text{Initial carrier frequency} = \frac{\text{Final carrier frequency}}{\text{Multiplication of doublers}} = \frac{41{,}000{,}000}{2^{12}} = 10{,}000 \text{ cycles per second}$$

It is not possible to modulate a 10,000-cycle carrier by an audio frequency of 15,000 cycles, since the audio frequency must be less than the carrier frequency. Therefore some modification of the system must be made. The modification adopted is to perform the modulation at an initial carrier frequency of the order of 200 kilocycles and pass it through a first group of say six doublers. The carrier frequency has then been multiplied 2^6 times and has reached a value of 12.8 megacycles. If now a final carrier frequency of 41 megacycles is desired, the 12.8 megacycle signal is combined with the output of a second crystal oscillator whose frequency is selected so that a beat note of $41/2^6$ or 0.6406 megacycle is obtained. This does not affect m_p. The 640.6-kilocycle wave is then passed through a second group of six doublers to obtain the final 41-megacycle output. Since the initial frequency-modulated wave has now passed through 12 doublers, the multiplication of 2^{12} or 4,096 has been obtained.

The output of the second group of doublers is then amplified up to the final power required.

While this circuit seems complicated, it should be remembered that these operations can be performed at low power and with receiving-type tubes. The cost is not prohibitive for a transmitter station, since the investment in other equipment would be much greater.

The second method of frequency modulation operates in a distinctly different manner. If the capacity of a capacitor could be varied at an audio rate, and if this capacitor were included in the tuned circuit of an oscillator, it is apparent that the output would be frequency modulated.

actance is that the current flowing into the two terminals is 90 degrees out of phase with the voltage applied across these terminals. This same effect can be secured with a tube circuit. The method is illustrated in figure 19. The resistance R_1 is made small in comparison with the reactance of C_1. Then the alternating voltage between the control grid and cathode is substantially 90 degrees out of phase with the voltage impressed across the terminals *a-b*. But the plate current which flows in the tube is determined largely by the grid voltage. The choke L_4 provides a large impedance to alternating current so that the a-c component of the plate current will flow in the terminals *a-b*. The current which flows into the terminals *a-b* will be 90 degrees out of phase with the voltage across it because of the grid control and the circuit appears like a reactance at these terminals.

The magnitude of the reactance is a function of the amplification constant of the tube. In a variable-mu tube the amplification constant may be controlled by the voltage on the grid. Therefore if an audio voltage is also impressed on the control grid of the tube the effective reactance may be varied at an audio rate.

The terminals *a-b* are connected in parallel with the tuned circuit L_3-C_3 of a conventional oscillator whose output frequency is determined by the resonance of that circuit. With this combination a variation in the audio voltage on the grid of the reactance tube will produce a frequency-modulated wave in the output circuit of the oscillator L_4-C_4.

The circuit of figure 19 does not have the inherent stability of the system of figure 18 because the carrier frequency or frequency for zero modulation is not crystal controlled. Stability equivalent to crystal control is necessary in modern radio operation. In order to secure crystal control a more elaborate system is necessary. This is illustrated by the block diagram of figure 20.

The oscillator and reactance circuit are similar to those of figure 19. The oscillator usually operates at some submultiple of the desired frequency, say one-fourth or one-sixth. A frequency multiplier is used before the operation of the final power amplifier, as is standard practice at ultrahigh frequencies. A sample of the output is brought back into a frequency converter where it is mixed with the output of a crystal oscillator for comparison purposes. The resultant beat note is then passed through a frequency discriminator of the same general type as used in receivers and illustrated in figure 17. If the final output changes frequency, the beat frequency passing into the discriminator will change. This change is used to produce a direct voltage in the discriminator which in turn is applied to the reactance tube to provide a correction on the frequency drift which has occurred.

This method of increasing stability has a marked similarity to the use of inverse feedback in audio amplifiers to increase their stability.

A delay or filter must be introduced in the frequency feedback circuit so that it is unresponsive to the variations in frequency produced by the audio modulation, but will make corrections for the long period drifts associated with oscillators which are not crystal controlled.

The two methods of frequency modulation transmitters each have their proponents. The Armstrong method is claimed to be more stable because the carrier frequency is directly controlled by the two crystals. The reactance tube method is simpler and would seem particularly applicable to low powers and portable equipment. It is too soon in terms of practical operation to be sure which will find the most general application.

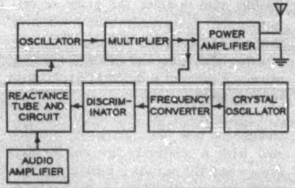

Figure 20. Block diagram of a reactance-tube-controlled frequency-modulated transmitter with crystal stabilization

The operation of the final amplifiers in both systems is essentially simpler than is the case in amplitude modulation, since attention need not be paid to the linearity of input-output amplitude curves.

In amplitude modulation the final high-power stage presents certain difficulties in operation. A transmitter normally requires[5] either a high-power audio amplifier with an output about 75 per cent of the rated carrier power to perform the modulation, or else the final stage must be operated at half its maximum efficiency. This is because in amplitude modulation the power output must be increased during modulation by an amount equal to the side-band power (50 per cent of the carrier power for $m=1.0$). The increase in power must be supplied by either an audio amplifier or by an increase in the efficiency of the output stage during the audio cycle. An increase in efficiency can only be obtained if the efficiency in the absence of modulation is limited to half its maximum possible value. Both of these expedients increase the cost of high-power stations materially. Since the amplitude and power output of an F-M transmitter are constant during modulation, the final stage can operate at its maximum efficiency at all times even though the original modulation is performed at a low power level where only receiving-type tubes are required.

The question is frequently raised whether the wide band which must be transmitted for F-M does not introduce difficulties in the tuned circuits. However, it should be remembered that the selectivity of any tuned circuits is given in terms of frequency ratio rather than absolute band width. A 200-kilocycle band width at 40 megacycles is only one-half of one per cent of the carrier frequency, while the 10-kilocycle band width used in standard broadcasting at 1,000 kilocycles is one per cent of the carrier frequency. Therefore no difficulties are introduced in the transmitter by the required absolute width of the band when the carrier frequency is high.

Application of Frequency Modulation to Services Other Than Broadcasting

Frequency modulation seems to have inherent advantages for other services than broadcasting. Important among these are its application to police and airway communication. The sharp limitation of the range obtained with F-M is an advantage and it would appear that many more police transmitters covering specific areas could be used without interference. In airway service some of the most important contacts are needed during severe electrical storms and F-M could make an important contribution in this field.

F-M would also appear to have advantages for military purposes where limited ranges are desired and interference is a particularly severe problem.

In police, airway, and military communication, high-quality reproduction is not necessary and so a more limited band would serve the purpose.

F-M has also been proposed for longer-distance communication by the use of relay or repeater stations spaced at intervals determined by the range of the transmitters. By the use of directional antennas this range can be increased. Previous proposals to use relay stations for broadcast-station interconnection have not met with favor because of the limited range and additional interference which they would cause, but it appears that a large part of this objection is eliminated when F-M is used.

It is also possible to multiplex other services on F-M transmission, such as facsimile, transmitting this service along with a sound signal, but with a reduction in the signal-to-noise ratio. Another suggestion has been to transmit two sound signals to obtain binaural reproduction. The possibilities of these uses have been only partially explored.

Conclusion

It would appear that frequency modulation is capable of producing a marked change in broadcasting within the next few years. It is very doubtful if it will eliminate the use of the standard broadcast frequencies, as they are still capable of covering larger distances when (and only when) a transmitter is given exclusive use of a channel. It seems probable that many local stations designed to cover a limited area will be transferred to F-M operation, and the number of cleared channels increased so as to take better advantage of the limited band of standard broadcast frequencies available. The development in these lines must eventually respond to the laws of economics and engineering.

Low-Voltage D-C Measurements on Electrical Insulating Oils

J. L. ONCLEY

W. C. HOLLIBAUGH
NONMEMBER AIEE

THE development work and experimental results presented herein have been a part of a co-operative project of the Utilities Co-ordinated Research, Inc. (Association of Edison Illuminating Companies) and the Massachusetts Institute of Technology. The purpose of this joint research project is the investigation of the mechanism of the deterioration of electrical insulating oils and the development of methods and apparatus for the study of this deterioration, with special reference to its influence on the electrical characteristics. It was for this reason that it was desirable to investigate the conductance of electrical insulating oils and methods of determining the conductance of such oils.

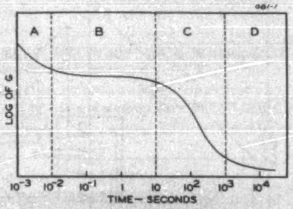

Figure 1. Variation of conductance with time at high gradients

General Considerations

In the usual conductance test for electrical insulating oils[1] the conductance is measured by means of a galvanometer used as an ammeter. A cell with a guarded electrode is used and from 500 to 1,500 volts potential difference is applied across the cell giving a potential gradient of from 200 to 1,200 volts per millimeter. The conductance (or resistance) is computed from the current reading one minute after the voltage is applied. As has been shown, principally by Whitehead,[2] this value is entirely empirical and often does not represent either the initial or the final conductivity of the oil. Using an amplifier-oscillograph and potential gradients of 500, 1,000, and 1,500 volts per millimeter Whitehead was able to measure the change of conductance with time from about 0.001 second after the application of voltage. The general type of the curve thus obtained for oils of low conductance is shown in figure 1.

Region *A* in figure 1 represents a brief initial decaying conductance indicating a phenomenon similar to dielectric absorption in solids. It has been suggested that it is due to the orientation of large polarized particles. Region *B* represents the true d-c conductance which is supposed to be due entirely to ions. It is this region which is of one to ten seconds duration in which we are most interested. Region *C* represents the time during which the ions are swept out of the space between the electrodes and space charges built up in the spaces near the electrodes. The empirical nature of the one-minute conductance value is easily understood since it falls in this region. Region *D* represents the long-time conductance after the "clean up" of the oil by the current which may take a period of hours to reach a constant value.

It was desired to find some more practicable and easier method than the amplifier-oscillograph arrangement by which to measure the true d-c conductance of region *B*. It was thought that the velocities of the ions could be reduced by reducing the potential gradient between the electrodes so that the true d-c conductance of region *B* would be extended from ten seconds duration to perhaps ten

minutes duration. If, for example, the potential gradient were reduced from the customary 1,000 volts per millimeter to 10 volts per millimeter the duration of the true d-c conductance would be extended from ten seconds to more than ten minutes.

Measuring Cell

It was further desirable to be able to make measurements of the d-c conductance using the same low-capacitance cell (approximately ten micromicrofarads capacitance) used in this laboratory for power-factor measurements. By doing this, both a-c and d-c measurements could be made on the same oil sample under identical conditions of cleaning and filling. This cell is shown in figure 2. It is a three-terminal cell which is so constructed that it may be completely taken apart for purposes of cleaning. The cell used in the work herein reported was made of stainless steel with nickel arms for filling. The cell was cleaned by three washings in technical benzene and then dried for one hour at 100 degrees centigrade with a continuous stream of nitrogen passing through, and finally cooled in a desiccator.

Bridge

Using a General Radio type 544 megohm bridge upon which various alterations had been made so as to increase its range and to allow it to operate at low bridge voltages, it was shown that this type of an arrangement was practicable for use with bridge voltages of from one to ten volts. With various desirable improvements in mind a new bridge was designed and built specifically for the purpose of making conductance measurements. This bridge has the same essential circuit as the General Radio megohm bridge and is shown diagrammatically in figure 3. It consists of a high-resistance Wheatstone bridge with a vacuum-tube amplifier and sensitive galvanometer as a detector. *B* and *N* are high-ratio arms, *B* with a maximum resistance of a megohm and *N* with a maximum of 1,000 megohms. The arm *A* is a decade resistance unit ranging from 0 to 10,000 ohms in 0.1-ohm steps. The measuring cell is placed in arm *P*, the measuring electrode being connected to the high terminal by a shielded lead. The shield of this lead together with the guard ring is connected to the guard terminal which is grounded. The entire assembly is mounted on an aluminum panel and placed in a shielded case, which is also grounded. All switches in the actual bridge circuit are made of low-loss yellow bakelite and connections where perfect insulation is essential are air-insulated bus wires.

The switching arrangement of the bridge is controlled by the switch indicated as *S*. This is a four-pole double-throw switch with the points bent so as to make contacts in the off position as
